A traditional viewpoint has been that inflammatory cells and mediators are neurotoxic, and that inhibition of inflammation will delay or prevent neuronal loss. Indeed, therapeutic trials of immunomodulatory agents in the mutant SOD1 mouse has supported this concept (Kriz et al., 2002; Keep et al., 2001; Kirkinezos et al., 2004). However, neuroinflammation is composed of multiple processes, working in series and parallel, which cumulatively can limit cellular injury and promote regeneration, or cause tissue damage and cell loss. An example of this is the dual role of prostaglandins, products of the COX-2 enzyme, in promoting either neuronal survival or apoptotic death. Determining factors may include the target cell and tissue environment, profile of specific prostaglandin(s), and the dose-dependent cellular response to the inflammatory mediators (Consilvio et al., 2004). In the mSOD1 mouse model, increases in COX-2 and PGE2 parallel motor neuron loss, and selective inhibition prolongs survival (Almer et al., 2002; Pompl et al., 2003), implying that COX-2 activation contributes to neuronal degeneration. However, looking at the cellular constituents rather than the biochemical effectors involved may provide greater insight into these processes.

Microglia are able to respond promptly to signals of stress or injury originating within or outside the CNS and direct

their responses for purposes of tissue repair and activation of immune responses. This appears to be regulated by neuron-astrocyte-microglia interactions which can either have stimulatory or inhibitory influences in shaping microglial and overall immune response (Aloisi, 2001). Further, microglia produce cytokines and molecules with both inflammatory (TNF α , IL-6, etc.) and anti-inflammatory (TGF- β , IL-10, neurotrophins, etc.) activity, and the balanced interplay between the two is crucial in the propagation or resolution of the inflammatory cascade (Aloisi et al., 2000; Tabakman et al., 2004). Certain factors, which may determine the outcome of this interplay, include the ability of microglia to function as antigen presenting cells, their interaction with antigen-specific T cells, the cytokine milieu, and their ability to sustain T cell growth. Although there is insufficient evidence to confirm that neuroinflammatory responses in ALS are also directed at repair, there is evidence from other CNS inflammatory models, which may provide direction in understanding the relevance of these processes in ALS.

In models of mechanical nerve injury, T lymphocytes have been shown to protect neurons, as evidenced by a greater loss of facial motoneurons after nerve transection in severe combined immunodeficient (*scid*) mice that lack T and B cells (Serpe et al., 1999). This protection is mediated by the T-cell generation of neurotrophic factors, such as brain-derived neurotrophic factor (BDNF) and neurotrophin-3 (NT-3) (Hammarberg et al., 2000). Furthermore, this neuroprotective effect is significantly boosted by myelin-specific T cells (Kipnis and Schwartz, 2002). This suggests that the ability to withstand the consequences of CNS axonal injury is governed by the ability to mount an endogenous Th1 cell-mediated protective response (Schwartz and Kipnis 2002). In animal models, this neuroprotective response can be achieved safely with low-affinity activation of T cells with synthetic altered myelin basic peptides, or copolymer, a synthetic compound of myelin basic protein (Angelov et al., 2003; Kipnis and Schwartz, 2002; Monsonego et al., 2003). Importantly, the beneficial T cell-mediated effect is dependent upon the early activation of microglia and their differentiation into efficient, antigen presenting cells (Shaked et al., 2004). Furthermore, the beneficial reparative effects may be directly mediated by microglial or astroglial release of neurotrophic factors, and indirectly mediated by T cell or dendritic cell signaling to glia.

In ALS, it is unknown whether a significant neuroprotective immune response is present, or if it plays a role in determining populations at risk, disease onset, or rate of progression. Clearly, the potential roles of T cell-, dendritic cell-, and microglia-mediated neuroprotection in neurodegenerative disease, including ALS, may become future targets of therapy. Copolymer 1 has already been shown to delay disease onset, improve life span, and improve motor activity in the mSOD1 mouse model (Angelov et al., 2003), and a phase I study of copolymer 1 has been studied for safety in the ALS population (Gordon et al., 2006). However, a randomized, placebo controlled trial is required to determine therapeutic efficacy.

Summary

There has been a profound paradigm shift regarding the potential importance of neuroinflammation in ALS. Once viewed as an epiphenomenon of motor neuron degeneration, neuroinflammatory changes are now considered to play an integral role in disease pathogenesis. A better understanding of how the cellular and biochemical components of this response affect motor neuron survival will enable us to develop new, immunomodulatory therapies. These novel therapies should be directed at amplifying those pathways involved in neuroprotection, while down-regulating cytotoxic pathways leading to motor neuron injury.

Acknowledgment. We are grateful to the Muscular Dystrophy Association for support of the ALS clinical and research programs at The Methodist Neurological Institute.

Review Questions/Problems

- Which of the following proposed pathogenic mechanisms in ALS are considered mutually exclusive (present in isolation) of other proposed mechanisms of disease?**
 - glutamate excitotoxicity
 - generation of free radicals
 - disrupted axoplasmic flow
 - altered calcium homeostasis
 - all of the above
 - none of the above
- Which statement best describes the meaning of 'non-cell autonomy' when referring to the pathogenesis of ALS?**
 - The risk of developing ALS is independent of cellular factors, and is more dependent on environmental exposures.
 - The progression of disease in ALS is dependent upon therapeutic intervention and early detection
 - Motor neuron injury is independent of interaction with other cell populations within the CNS
 - Motor neuron injury is dependent on interaction with other affected cell populations within the CNS
- Which line(s) of evidence from human studies support that the immune inflammatory response in ALS has a role in amplifying disease progression?**
 - Increased expression of myeloid dendritic cells mRNA transcripts in ALS spinal cord that correlates with a faster rate of progression
 - Increased mRNA expressions of the chemokine MCP-1, and the cytokine macrophage-colony stimulating factor (M-CSF) in ALS spinal cord, which attracts and induces differentiation of monocytes and myeloid dendritic cells, respectively.

- c. Both a and b
d. Neither a or b
- 4. Which line(s) of evidence from animal and *in vitro* studies support that the immune inflammatory response has a role in motoneuron injury?**
- a. Studies from mSOD transgenic chimeric mice showing that mSOD expressing neurons that are surrounded by wild-type glial cells remain intact
b. Motoneuron injury by activated microglia mediated by glutamate and peroxynitrite
c. Both a and b
d. Neither a or b
- 5. The failure of immunosuppressive therapy in ALS is sufficient evidence that immune mediated mechanisms are not relevant to disease pathogenesis.**
- True/False
- 6. The higher incidence of autoimmune diseases and paraproteinemias in ALS patients confirms that sporadic motor neuron disease is autoimmune in nature.**
- True/False
- 7. Association between viral infection and motor neuron disease is based upon cases of motor neuron disease due to retroviral infection (HIV, HTLV-1) and the presence of serum antibodies directed toward endogenous retroviral gene sequences in ALS patients.**
- True/False
- 8. In CNS injury, the neuroprotective response of activated T cells is dependent upon early activation and differentiation of microglia into antigen presenting cells which release neurotrophic growth factors.**
- True/False
- 9. Although human and animal studies support a role for immune responses in ALS pathogenesis, which statement(s) are reasonable explanations for why immunosuppressive therapy has failed in treating ALS?**
1. Immune suppressive therapy is initiated beyond the point when motor neuron recovery and clinical improvement are possible.
2. Inadequate access to or suppression of immune inflammatory cells in the CNS
3. Suppression of both cytotoxic and protective immune mechanisms
4. Immune inflammation does not contribute to ALS disease pathogenesis
a. 1, 2, 3
b. 1, 3
c. 2, 4
d. 4 only
e. All of the above
- 10. Which of the following patient variables are associated with a poor prognosis?**
1. Older age of onset
2. Female gender
3. Bulbar onset
4. Sporadic form
a. 1, 2, 3
b. 1, 3
c. 2, 4
d. 4 only
- 11. Slurred speech, excessive salivation, and hoarseness may be the presenting feature in what percentage of ALS patients?**
- a. 15%
b. 25%
c. 35%
d. 45%
- 12. Cognitive dysfunction is not a typical feature of ALS.**
- True/False
- 13. A clinical diagnosis of ALS requires the demonstration of lower motor neuron involvement in which three areas?**
- a. upper extremity limb, eye muscles, and paraspinal muscles
b. lower extremity limb, eye muscles, and tongue
c. upper extremity limb, tongue, paraspinal muscles
d. lower extremity limb, upper extremity, eye muscles
- 14. Studies of which disease have provided an increased understanding of the interactions between neurology and immunology?**
- a. Mollaret's Meningitis
b. Guillan Barre Syndrome
c. poliomyelitis
d. multiple sclerosis
- 15. The presence of an increased number of dendritic cells in ALS tissues provides evidence for activation of an innate immune response.**
- True/False
- 16. The following molecules enhance the entry of leukocytes from the periphery into areas of injury and have been observed in ALS tissues.**
- a. MCP-1, LFA-1, ICAM-1, AND MMP-9
b. COX-2, GFAP, ICAM-1 MMP-9
c. M-CSF, MCP-1, COX-2, MMP-9
d. COX-2, M-CSF, ICAM-1, MCP-1
- 17. MCP-1 is a chemokine, which attracts monocytes and myeloid dendritic cells to sites of injury or inflammation.**
- True/False

18. *In vitro*, motor neuron injury is induced by exposure to activated microglia. Which microglial constituents initiate such injury?

1. kainite and IgG
2. mSOD1 and peroxynitrite
3. glutamate and IgG
4. peroxynitrite and glutamate
 - a. 1, 2, 3
 - b. 1, 3
 - c. 2, 4
 - d. 4 only

19. The failure of immunosuppression to ameliorate type-1 diabetes or chronic progressive multiple sclerosis, predominantly immune mediated diseases, invalidates the role of immune mechanisms in initiating these disorders.

True/False

20. Prostaglandins have a dual role in either promoting neuronal survival or apoptotic death. What factors may determine which role predominates in CNS injury or degeneration?

1. Target cell and tissue environment, degree of cellular response to the inflammatory mediators, and profile of specific prostaglandin(s)
2. Exposure to prostaglandin and cox-2 inhibitors, target cell and tissue environment, and profile of specific prostaglandins(s)
 - a. both 1 and 2
 - b. neither 1 or 2
 - c. 1
 - d. 2

Huntington's Disease

Seymour Gendelman, Howard E. Gendelman, and Tsuneya Ikezu

Keywords Huntingtin (htt); CAG repeats; Chorea; Medium spiny neurons (MSNs)

28.1. Introduction

Huntington's disease (HD) is a familial and rare inherited neurological disorder with a prevalence of 5–8 cases per 100,000 worldwide. This makes HD the most common inherited neurodegenerative disorder (Fahn, 2005). HD is passed from parent to child in autosomal dominant fashion. Each child of an HD parent has a 50% chance of inheriting HD. Both sexes are affected equally. It is amongst the first inherited genetic disorders where an accurate test is now available. The disease complex is ascribed to George Huntington who in 1872 described the clinical and neurological manifestations. The neuronal degeneration causes uncontrolled and abnormal body movements called chorea, mental dysfunction, personality changes, and emotional disturbances. Neuropathologically, HD is associated with the death of GABAergic medium sized spiny projection neurons in the caudate nucleus and to neurons in other brain regions. The HD gene, huntingtin (htt), is located on the short arm of chromosome 4, contains N-terminal 18 amino acid-encoding open reading frame, followed by expanded CAG trinucleotide repeat which encodes variable length of poly glutamine tract, and large C-terminal region (>3,100 amino acids). The length of the HD CAG repeats is the primary determinant of the age at which clinical symptoms will appear (Persichetti et al., 1994). Although it is commonly known that the HD polyglutamate tract leads to formation of intracellular inclusions in cytoplasm and/or nucleus in a number of tested species, the correlation of the inclusion with neurotoxicity has been extremely variable. However, the increased number of glutamine is accompanied by the propensity of full-length htt protein to misfold and aggregate; therefore HD belongs to the class of protein misfolding/aggregation disorders. Early HD symptoms are seen in a person's forties, but can occur at any age. Symptoms include mood swings, depression, irritability, difficulties in learning and remembering, and in decision making. As the

disease progresses, concentration becomes difficult and daily tasks of maintaining one's self are all but gone; also individuals have difficulty feeding and swallowing. Death in HD typically occurs around 15 years after motor onset due to complications of the disorder, such as aspiration pneumonia. Presymptomatic testing is available for individuals who are at risk for carrying the HD gene. There is no known treatment that alters the course of the disease, but symptoms can be managed.

28.2. History

There are at least five reports predating the description of HD by George Huntington's paper published in the *Medical and Surgical Reporter* on April 12, 1872 (reviewed by Bruyn and Went, 1986). HD was recognized by Charles Waters in 1841 in a letter published by Dunglison in his "Practice of Medicine" and was suggested in the 1846 thesis presentation "On a Form of chorea vulgarly called magrums" by Charles Gorman to the Jefferson Medical College Commentary in 1908 (history reviewed in Harper, 1996). In 1860 Norwegian physician, Dr. Christian Lund wrote another HD report (Folstein, 1989; Harper, 1996). His paper described a hereditary form of St. Vitus Dance.

In 1983 the mutant gene was localized to the short arm of chromosome 4 (Gusella et al., 1983). Subsequent predictive value required the acquisition of both parent's DNA for evaluation (Gusella et al., 1983, 1984; Wexler et al., 1985). A major breakthrough came in 1993 with gene discovery—IT15 (Interesting Transcript 15). It was found to be an expansion of a CAG (Cytosine Adenosine Guanine) trinucleotide repeat, which codes for glutamine, at 4p16.3 (Huntington's Disease Collaborative Research Group, 1993; Ross, 1995; Zoghbi and Orr, 2000). A major contribution to the localization and isolation of the gene was from the "Venezuela Project," a comprehensive study of family clusters of HD that has been ongoing for more than four decades (Folstein, 1989; Harper, 1996). Since discovery of the gene, research on the etiology, pathophysiology, biochemistry, polyglutamine toxicity, and potential therapies has greatly intensified.

28.3. Epidemiology

HD involves all ethnic groups and is most frequent in patients of Caucasian descent (Harper, 1996). Transmission of the genetic defect that causes HD came to North America was probably through the seafaring colonial powers—England, France, Netherlands, Portugal and Spain—in the seven-teenth and eighteenth centuries and then throughout the world (Hayden, 1981; Folstein, 1989). Various migration patterns are certainly a major factor in the appearance of the disease in South Africa and Australia (Folstein, 1989; Goldberg et al., 1996). On the other hand, HD is rare in Japan (approximately 10% of the prevalence in the United States) and in African blacks (in contrast to American blacks and mixed races) (Folstein, 1989; Harper, 1996). Significant foci of families have been noted in Britain, Canada, Sweden, Venezuela, and the United States (Hayden, 1981; Folstein, 1989). Special mention should be made of the Venezuelan occurrence around Lake Maracaibo and the important role of those studies in mapping and isolating the gene for HD (Bruyn and Went, 1986).

28.4. Genetics

The HD gene, *Htt*, was first discovered in 1983 (Gusella et al., 1983), due to and the link between the disease development and the number of CAG repeats (HD Collaborative Research

Group, 1993; Ranen et al. 1995; Margolis and Ross, 2001). The gene contains 67 exons and encodes the protein Htt, which is about 350 kDa long, contains 3,144 amino acids, and has no homology with other known proteins (Huntington’s Disease Collaborative Group, 1993; Margolis and Ross, 2001). Normal *Htt* contains less than 29 trinucleotide repeats. In most patients with HD, *Htt* gene contains more than 35 repeats of polyglutamine (polyQ) sequence (Ranen et al. 1995; Rubinsztein et al., 1996; Margolis and Ross, 2001; Fahn, 2005) and has 100% penetrance. There is an intermediate group of CAG repeat lengths, 29–35, for which penetrance rates have been difficult to establish due to their infrequent occurrence. HD is a member of the polyglutamine disorders characterized by an unstable CAG trinucleotide repeat including SCA 1,2,3, Machado-Joseph disease, (MJO), 6, 7, 12, 17, dentatorubral-pallidoluysian atrophy (DRPLA), Spinobulbar muscular atrophy (SBMA), and Kennedy’s disease (Rubinsztein, 2002) (Figure 28.1).

By 1986, it was noted that patients with a clinical onset prior to age 20 had a preponderant inheritance from affected fathers (Harper, 1996; Fahn, 2005). In those patients with onset prior to 10 years, the incidence approaches 100% (Hayden, 1981). The CAG repeats were found to be unstable in gametes and with high repeat trinucleotide lengths (Riley and Lang, 1991; Duyao et al., 1993; Fahn, 2005). The instability in sperm DNA may explain the increased number of repeats in successive generations of male derived offspring—“anticipation” (Duyao

FIGURE 28.1. Protein context of the polyglutamine expansion determines which neuronal cell populations are the most vulnerable. Shown is the location of the polymorphic polyglutamine tract in nine different protein contexts (drawn to scale) that, when expanded, causes the specific loss of neurons from different brain regions and lead to distinct inherited neurodegenerative disorders [cited from Gusella and Macdonald (2006). *Huntington’s disease: seeing the pathogenic process through a genetic lens. Trends Biochem Sci* 31, 533–40 (2006) with permission from Elsevier].

FIGURE 28.2. Correlation of HD CAG-repeat length with age at onset. Best-fit curves for age at neurological onset (red) and duration of disease from onset to death (blue), plotted against CAG-repeat length for the expanded mutant allele from Huntington disease (HD) patients. Age at onset is strongly correlated with the CAG-repeat length ($r^2 = 0.54$; $p < 0.001$), whereas duration of disease shows no correlation with the CAG-repeat length, suggesting that factors independent of the original trigger of pathogenesis predominate after onset of HD to determine rate of progression [cited from Gusella and Macdonald (2006). ME. *Huntington's disease: seeing the pathogenic process through a genetic lens. Trends Biochem Sci* 31, 533–40 (2006) with permission from Elsevier].

et al., 1993; Andrew et al., 1993; Ranen et al. 1995; Harper, 1996; Margolis and Ross, 2001; Fahn, 2005). Affected females tend to transmit approximately the same number of repeats (that is, there is an equal probability of increased or decreased repeats); whereas, males tend to transmit a greater (rather than lower) number of repeats (Duyao et al., 1993; Margolis and Ross, 2001; Fahn, 2005). The length of the repeat contributes to the age of onset of symptoms: the greater the number of repeats, the earlier the age of onset (Figure 28.2) (Rubinsztein, 2002). This applies equally to male and female offspring (Harper, 1996; Fahn, 2005). Most adult-onset patients carry 40–50 CAG repeats, whereas greater than 55–60 CAG repeats are more likely to express the juvenile form of HD (Rubinsztein, 2002; Fahn, 2005). The numbers of spontaneous mutations appears to be somewhat greater than initially anticipated, based on increased identification of sporadic cases through DNA analysis (Riley and Lang, 1991; Fahn, 2005).

Homozygotes and heterozygotes have a similar age of onset, though the former, which are very rare, generally experience a much more fulminant course, reflecting a double dose of the abnormal trinucleotide expansion (Harper, 1996; Fahn, 2005). It has not been fully determined that longer repeat patients have a greater rate of progression, though postmortem studies show a greater degree of pathological changes (Kiebert et al., 1994; Furtado et al., 1996).

28.5. Pathology

The hallmark of HD pathology is the striking regional atrophy and neuronal loss in the striatum (caudate nucleus and putamen) (Roos, 1986; Margolis and Ross, 2001). Macroscopically the brain shows atrophy, predominant in the striatum, with marked ventricular dilatation, and approximately 25–30% decrease in brain weight (Margolis and Ross, 2001). White matter and cortical atrophy are evident in more advanced cases.

Microscopically there is selective loss of small-medium-sized spiny type II neurons with relative sparing of the large neurons of the striatum (Hayden, 1981; Roos, 1986; Margolis and Ross, 2001). There is an associated variable degree of gliosis (Roos, 1986). The earliest and most severe loss is in dorsal and medial regions with progressive severe loss of neurons to the ventral and lateral regions (Harper, 1996; Margolis and Ross, 2001). Other regions of the basal ganglia and areas of the thalamus, cerebellum, brainstem, and spinal cord are affected to a lesser degree (Roos, 1986). The cerebral cortex is also affected, especially the large pyramidal neurons in layers III, V and VI (Roos, 1986; Harper, 1996; Margolis and Ross, 2001).

Striatal atrophy is progressive and may be so severe as to leave the striatum devoid of any cells. In a study comprising 154 HD patients, a classification of pathologic severity was developed based on the degree of striatal cell loss (Vonsattel et al., 1985). Those patients with greater neurodegenerative changes tend to have more severe clinical disease and earlier age of onset as well as a larger number of trinucleotide repeats (Myers et al., 1988; Furtado et al., 1996; Fahn, 2005). Some surviving neurons show evidence of regeneration in dendrites while other neurons are selectively spared (Graveland et al., 1985; Ferrante et al., 1985). The major losses of cortical neurons are those, which project to the thalamus and striatum [superior regions of cortical layer VI; (Margolis and Ross, 2001)]. There is no close correlation between the degree of striatal degeneration and cortical neuronal loss and as such neuropathogenic events may not be wholly secondary to retrograde degeneration (Margolis and Ross, 2001). Analysis of postmortem human HD brain tissue using antibodies directed at the N-terminus of Htt shows intranuclear inclusions in neurons but not glia, most abundant in cortical layers III, V, and VI, and the medium spiny neurons (MSNs) of the striatum. The density of the inclusions correlates with the length of the CAG repeat. However, the inclusions cannot be identified by antibodies directed at internal epitopes of Htt but can be detected (both in full-length wild type and mutated Htt) by immunofluorescence and biochemical fractionation (Margolis and Ross, 2001; Truant, 2003). This suggests that the complete protein may be misfolded in the nucleus as inclusions. Similar inclusions have been detected in transgenic mouse models of HD (Davies et al., 1997; Rubinsztein, 2002). Biochemically, the striatal loss correlates with decreased concentrations of gamma-aminobutyric acid (GABA), glutamic

acid decarboxylase (GAD), enkephalin, and substance P (Hayden, 1981; Roos, 1986; Martin and Gusella, 1986). There is relative sparing of cholinergic and somatostatin striatal interneurons (Fahn, 2005) but decreased acetylcholine (ACh) and dopamine (DA) receptors in the striatum (Folstein, 1989). This probably results in decreased DA inhibition, increased DA and tyrosine hydroxylase (T-OH) in the substantia nigra, and decreased binding of GABA in the striatum (Roos, 1986; Martin and Gusella, 1986; Folstein, 1989). Neuropeptide Y and somatostatin are increased with relative sparing of their cells of origin in the nucleus accumbens and ventral striatum (Roos, 1986; Martin and Gusella, 1986; Harper, 1996).

N-methyl-D-aspartate receptors (NMDAR) are severely reduced in the striatum and cerebral cortex, suggesting an excitotoxic mechanism for the pathogenesis of HD (Folstein, 1989; DiFiglia, 1990; Fahn, 2005). This is based on the observation that infusion into the brain of glutamate-receptor agonists induces neuronal death and disease manifestations similar to HD (Beal et al., 1986; Vonsattel and DiFiglia, 1998; Bates et al., 2002). Deficits in mitochondrial metabolism were reported in the brains of patients with HD providing another disease hypothesis (Beal, 1998). Caspases, proteases known to be involved in apoptotic cell death are increased in HD, and may participate in neurodegenerative activities (Wellington et al., 1998; Ona et al., 1999;). Htt sequester proteins such as transcription factors, heat-shock proteins, and proteasome subunits may affect the functions of a number of normal neuronal proteins (Davies et al., 1997; Ross et al., 2003).

28.6. Clinical Course

28.6.1. Natural History

Huntington's disease, an autosomal dominant disease affecting males and females equally, is characterized by a triad of major clinical findings: abnormal involuntary movements, personality/behavioral disorder, and cognitive deterioration to dementia (Bruyn and Went, 1986; Folstein, 1989; Harper, 1996; Hayden and Leavitt, 2000; Fahn, 2005). Difficulties in diagnosis arise when there is sporadic disease or an incomplete family history (i.e. adoption or family separation). Though the general age of onset is between 35–45 years (mean age of 40) the range may be from children to the 80s (5% before age 20 and 5% after age 60) (Bruyn and Went, 1986; Folstein, 1989; Riley and Lang, 1991; Hayden and Leavitt, 2000; Margolis and Ross, 2001). Duration of disease usually approximates 15 years (14–20) (Bruyn and Went, 1986; Martin and Gusella, 1986; Harper, 1996). The symptoms may arise almost simultaneously or be spread over years. The behavioral features may be present for years and not considered pathologic prior to the appearance of cognitive decline motor abnormalities. Often the initially noted features are motor—typically of the hyperkinetic involuntary type, choreatic or myoclonic jerking

movements, with “cover-up” attempts by the patient to reduce attention to the movement from observers (Bruyn and Went, 1986; Fahn, 2005). The initial onset may be general clumsiness, motor impersistence (the inability to continue an ongoing movement), awkward gait, dropping things, or movements resembling tics. These movements may later progress to overt chorea, myoclonus, dystaxia, and ceaseless writhing, twitching or uncoordinated movements (Bruyn and Went, 1986; Martin and Gusella, 1986; Harper, 1996). Sensation is usually not involved (Hayden and Leavitt, 2000; Fahn, 2005).

The ocular, orofacial, and speech abnormalities may begin with incomplete saccades and difficulty in visual tracking (Bruyn and Went, 1986). Facial movements include appearances of whistling, blowing out of cheeks, facial grimacing, or protruding tongue for a brief period (Harper, 1996; Fahn, 2005). Speech may be altered by abnormalities of oropharyngeal muscles as in repetition of brief sounds (Bruyn and Went, 1986; Folstein, 1989; Hayden and Leavitt, 2000). The more obvious movements may be difficult to separate from other movements as ballism, tardive dyskinesia, or athetosis (Bruyn and Went, 1986). The association with varied stereotyped movements as chorea, myoclonus, general clumsiness, and ataxia help define the situation. Initially the movements are mistaken for tics but the random appearance of chorea is the most striking movement abnormality (Bruyn and Went, 1986; Fahn, 2005) with quick brief movements of proximal, distal, or trunkal muscles. There is gradual development of an awkward, arrhythmic—almost “dancing”—broad-based gait and inability to hold a steady course, lurching to either side with loss of tandem gait (Bruyn and Went, 1986; Hayden and Leavitt, 2000; Fahn, 2005). When attempting to maintain a sustained grip, there are sustained contractions interrupted by sudden relaxations or pauses (“milking grip”) (Bruyn and Went, 1986). Ultimately there may be increased tone and even signs of pyramidal dysfunction with clonus and extensor plantar responses, progressing to loss or diminution of choreiform movements and progression to rigidity and dystonia (Folstein, 1989; Hayden and Leavitt, 2000). Terminally patients become incontinent of bowel and bladder and bedridden, unable to perform most aspects of self-care. A disparity may exist in the clinical picture of HD between children and adults (Bruyn and Went, 1986; Hayden and Leavitt, 2000). The juvenile form (Westphal variant, occurring in 5% of patients) is characterized by a fulminate course, rigidity and dystonia progressing to akinesia (Bruyn and Went, 1986). Seizures are common, occurring in more than one-third of younger patients. There is more frequent oculomotor involvement and more rapid decline in cognition (Bruyn and Went, 1986; Hayden and Leavitt, 2000). Chorea is uncommon (Rubinsztein, 2002). Death is usually due to aspiration and respiratory failure. Suicide may be more common in HD at all age groups (Bruyn and Went, 1986; Folstein, 1989; Hayden and Leavitt, 2000; Harper, 1996; Fahn, 2005).

28.6.2. Personality—Behavioral Disorder

Onset of behavioral changes may be quite subtle and difficult to recognize. Time of onset is even more difficult to place. Changes may be interpreted as a reaction to ongoing symptoms but gradually become more overt. In contrast to earlier beliefs that the majority of these behaviors were reactive, more detailed studies have shown these to be distinct neurochemical disorders (Folstein, 1989; Margolis and Ross, 2001). The neurobehavioral disorder has been broadly categorized into abnormalities of arousal, attention, affect, perception, cognition, and personality. Depression, often with progression to frank psychosis, is a more common presentation. There is an initial decrease in interest, lateness at work, taking longer to complete tasks, and withdrawal from family and social interactions (Martin and Gusella, 1986; Folstein, 1989; Goldberg et al., 1996; Hayden and Leavitt, 2000). Irritability, abrupt behaviors and, infrequently, aggressive behaviors are seen (Folstein, 1989; Fahn, 2005). Short temper and tendency to overt obsessive-compulsive behaviors may exist (Bruyn and Went, 1986; Margolis and Ross, 2001). Both apathy and irritability may occur together. Frank psychotic behavior resembling schizophrenia with prominent delusions, hallucinations, and paranoid ideation may occur (Bruyn and Went, 1986; Folstein, 1989; Hayden and Leavitt, 2000; Margolis and Ross, 2001; Fahn, 2005). The psychologic manifestations may respond to specific anti-psychotic, antidepressant or anti-anxiety agents, but there is no treatment to slow the progression of the behavioral changes. Sexual function may be diminished, at times with complaints of impotence. More rarely aggressive sexual behavior occurs (Folstein, 1989). Hospitalization may be necessary because of progressive behavior changes, debilitation, and an inability to provide adequate home care (Bruyn and Went, 1986; Fahn, 2005; Folstein, 1989).

28.6.3. Cognitive Deterioration

Though often intertwined with behavioral aspects, cognitive decline is generally similar to that of the dementias and more difficult to characterize as a distinct diagnostic pattern (Fisher et al. 1983). There is early memory impairment, errors in judgment, poor arithmetic skills, and general mental slowing. Problem solving becomes more difficult, job performance deteriorates, and household responsibilities are unfulfilled. There may be language deficits with or without evidence of aphasia (Folstein, 1989). Despite the cognitive progression, perceptive functions remain generally intact (Bruyn and Went 1986; Martin and Gusella, 1986; Folstein, 1989; Harper, 1996; Margolis and Ross, 2001; Fahn, 2005). Visual memory may be retained until late in the disease. Finally patients may become mute, verbally unresponsive, and progressively apathetic, with a more global rather than subcortical dementia (Bruyn and Went, 1986; Folstein, 1989).

28.6.4. Laboratory

Computerized tomography (CT) or magnetic resonance imaging (MRI) demonstrate enlarged ventricles and usually a striking shrinkage of the caudate nuclei in their ventral paraventricular location, resulting in characteristic ventricular widening in the area of the caudate atrophy. Recent MRI scans of preclinical subjects with HD gene expansions, demonstrate a significant rate of atrophy years prior to their predicted clinical onset (Aylward et al., 2004).

Single photon emission tomography (SPECT) demonstrates reduced blood flow in the area of the caudate and putamen (Harper, 1996). Positron emission tomography (PET) shows reduced glucose metabolism in the striatum (Folstein, 1989; Harper, 1996; Fahn, 2005). Functional MRI (fMRI) shows reduced subcortical (region of caudate and thalamus) participation in a time-discrimination task in preclinical HD subjects (Paulson et al., 2004).

Genetic testing for the HD gene is now widely available to confirm or deny suspected diagnosis. Special care and genetic counseling by knowledgeable and experienced specialists is a crucial component of the testing process. Genetic testing, though relatively straightforward (The World Federation of Neurology Research Group on Huntington's Disease, 1993), carries a number of potential problems (Creighton et al., 2003). When a result of CAG expansion is in the intermediate range, the test should always be repeated. More importantly, there should be careful screening prior to any testing (International Huntington Association and the World Federation of Neurology Research Group on Huntington's Chorea, 1994). How the disease is inherited need to be made very clear. Further, genetic counseling before and after testing must be offered and required prior to further considerations (Folstein, 1989; Riley and Lang, 1991; Fahn, 2005). Psychiatric and/or psychological evaluations should be strongly considered (Folstein, 1989). Legal, ethical and emotional issues are major considerations for predictive testing and should be performed by well-trained and experienced groups. Early knowledge of the disease is also important in regards to treatments as therapeutic trials are being performed in presymptomatic patients as well as those already affected (Hersh, 2003; Taylor, 2004).

28.6.5. Diagnosis

The clinical picture is usually the earliest tool for diagnosis in the adult. A detailed family history, clinical triad, and clear imaging often establish the diagnosis. Gene testing offers the most accurate diagnosis. In the absence of confirmatory gene testing, a differential diagnosis list may need to be considered. HD is a CAG trinucleotide repeat disease in a family of similarly derived diseases including Machado-Joseph disease (SCA-3), a number of spino-cerebellar ataxias (Gusella et al., 1984; Wexler et al., 1985; Bruyn and Went, 1986; Duyao et al., 1993; Harper, 1996; Fahn, 2005). Kennedy's disease, and dentatorubral-pallidoluysian atrophy (DRPLA) (Folstein, 1989; Ravikumar et al., 2003). There are a number

of HD-like diseases that ultimately require gene testing for differentiation, including DRPLA in the group manifesting chorea (Harper, 1996; Margolis and Ross, 2001; Fahn, 2005). Neuroacanthocytosis can be difficult to distinguish from HD but atypical retinitis pigmentosa, peripheral neuropathy and the abnormal RBC can be helpful (Fahn, 2005). Adult HD patients may experience seizures early in the disease (Bruyn and Went, 1986). All of the Htt polyglutamine expansion diseases share the characteristics of ataxia and varying degrees of dementia (Harper, 1996; Margolis and Ross, 2001). Other trinucleotide repeats, i.e. CTG repeat in HDL2, may share phenotypic expressions (Fahn, 2005).

Sydenham's chorea occurs at an earlier age than adult onset chorea in HD, is self-limited in its course, and lacks other HD characteristics. Choreiform movements may also occur in systemic lupus erythematosus, tardive dyskinesia, and the dyskinesias due to levodopa toxicity in Parkinson's disease. Brain imaging may be very helpful in these circumstances (Osborn, 1994). Creutzfeldt-Jakob disease can show myoclonus and dementia over a relatively rapid period, while multi-system atrophy may present a complicated array of symptoms, though autonomic abnormalities generally appear quite early. The dementias pose a differential problem early on. Alzheimer patients are usually devoid of motor abnormalities, and language difficulties may help differentiate the diagnosis. Subcortical dementias may pose a problem early but should be differentiated with imaging and progression of the disease. The fronto-temporal dementias may manifest with very early, almost isolated, language deficits.

28.6.6. Treatment

Treatment at present is only symptomatic. Appropriate drugs for depression, agitation, irritability, anxiety, or frank psychosis may manage the psychiatric and psychological problems. The motor difficulties may be more complicated and harder to control. Muscle relaxants of central origin and GABAergic medications have not proven to be overly helpful. Neuroleptic agents may partially control the chorea but may cause tardive dyskinesia or enhance cognitive dysfunction in sedated patients.

28.7. Mechanisms of Cell Death

28.7.1. Neurotoxicity

Neurotoxicity in HD has long been thought to reflect a "gain of function" effect of the mutation (i.e. gain of a toxic function by the affected protein, rather than loss of a normal function), leading to excessive neuroexcitation and cell death (Hayden, 1981; Bruyn and Went, 1986; Harper, 1996; Hayden and Leavitt, 2000). Other mechanisms, either related or coincident with neuroexcitotoxicity, have been explored since the discovery of the HD gene (Hayden, 1981; Hayden and Leavitt, 2000; Raymond, 2003). Much of this exploration has involved the

availability of animal, cell, and neurotoxic models as well as transgenic models (Rubinshtein, 2002; Raymond, 2003; Wellington and Hayden, 2003; Fahn, 2005). Examples of neurotoxic models used to define pathogenesis, mechanisms, and potential therapeutic interventions include quinolinic (Beal et al., 1989) or kainic (McGeer and McGeer, 1976) acid injections into the striatum, or peripheral injections of 3-nitropropionic acid (Beal et al., 1993) in attempts to produce aspects of HD (Margolis and Ross, 2001; Raymond, 2003). The resultant toxicities provided the first evidence suggesting a pathogenic role for excitotoxicity (Margolis and Ross, 2001; Raymond, 2003). Both produced death of medium spiny neurons (MSNs), sparing the large aspiny interneurons in the striatum (Coyle and Schwartz, 1976; McGeer and McGeer, 1976; Margolis and Ross, 2001; Raymond, 2003). In addition, chronic MSN loss induced by 3-nitropropionic acid mitochondrial toxicity is attenuated by NMDAR antagonists (Beal et al., 1993; Raymond, 2003). The results suggest that excessive NMDAR activity with mitochondrial dysfunction may play a major role in striatal MSN death in HD (Margolis and Ross, 2001; Raymond, 2003).

The biochemical loss of GABAergic projection MSNs with preservation of the large aspiny interneurons containing acetylcholinesterase or nitric oxide synthase (NOS), neuropeptide Y and somatostatin is the pattern seen in HD (Ferrante et al., 1985, 1987; Graveland et al., 1985; Margolis and Ross, 2001). These neurotoxic experiments also suggest involvement of metabolic pathways with free radical damage that promote apoptotic progression to cell death triggered by caspase activation and altered GAPDH (glyceraldehyde-3-phosphate dehydrogenase) function (Utz and Anderson, 2000; Wolozin and Behl, 2000; Margolis and Ross, 2001). Free radical tissue damage plays an important role for other CNS diseases, including amyotrophic lateral sclerosis and Parkinson's disease (Facchinetti et al., 1998). Evidence of mitochondrial dysfunction and free radical activation has been found in human HD brain tissue (Browne et al., 1997; Koroshetz et al., 1997).

28.7.2. Biological Function of Htt

Htt protein is composed largely of convective HEAT repeats, which are around 38 amino acid degenerate motifs named for their presence in Htt, Elongation factor 3, protein phosphatase 2A regulatory subunit A, and target of rapamycin 1 (TOR1) (Andrade and Bork, 1995). Based on the HEAT structure, htt has been suggested to function as a scaffold, organizing members of dynamic complexes for transport and/or transcriptional activity. In addition to the HEAT motifs, many polyQ-containing proteins seem to play a role in protein-protein interactions and regulation of neurogenesis, suggesting that the polyQ regions could be sites for transcriptional alteration (Davies et al., 1997; Margolis et al., 1997; Margolis and Ross, 2001; Sawa et al., 2005). Normal Htt may actually have some anti-apoptotic function, in that reduced levels may contribute to neuronal degeneration (Rigamonti et al. 2000; Leavitt

et al., 2001; McMurray, 2001; Wellington et al., 2002). The htt interaction with specific regulators must at least in part occur in the nucleus, and then also plays a role in nuclear entry (Ross, 1997; Margolis and Ross, 2001; Luthi-Carter and Cha, 2003; Truant, 2003). Normally htt is present in cytoplasm with only a small fraction present in the nucleus, in contrast to the disease state (Davies et al., 1997; Di Figlia et al., 1997; Kegel et al., 2002; Luthi-Carter et al., 2003; Truant, 2003). The interaction of transcription-linked proteins and DNA sequences as well as the possible role of mutant htt has been extensively studied (Landles and Bates, 2004). Of the transcription pathways that are affected in HD, the cAMP-responsive element (CRE)-

and the specificity protein 1 (SP1)-mediated pathways are the most extensively studied. This owes to their involvement in the expression of gene needed for neuronal survival. Numerous accounts have shown that transcriptional factors such as p53, CREB-binding protein (CBP), SP1, and TATA-binding protein (TBP) can be sequestered into intranuclear aggregates, thus reinforcing the hypothesis of a role of transcriptional dysregulation in HD. Also, the accumulation of chaperones, proteasomes, and ubiquitin in polyQ aggregates suggests that insufficient protein folding and degradation are implicated in the HD pathogenesis (Sakahira et al, 2002; Ciechanover and Brundin, 2003) (Figure 28.3).

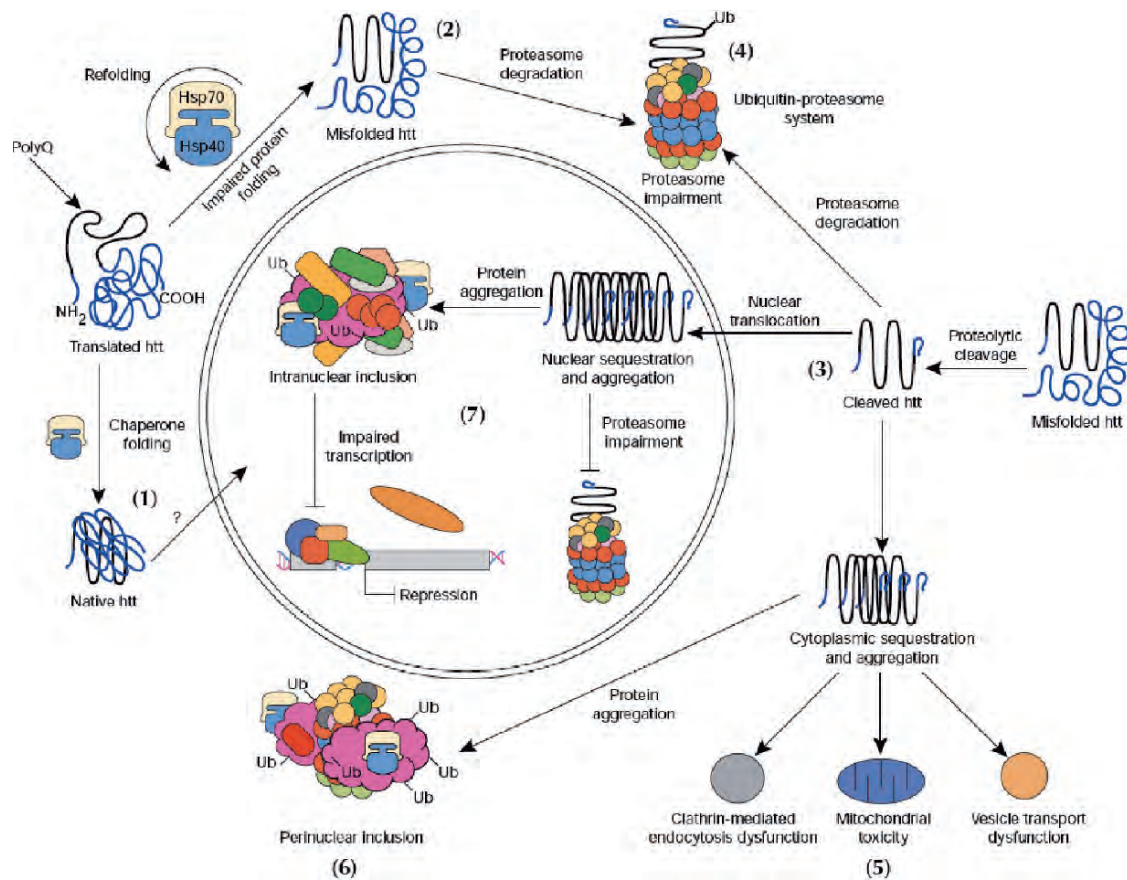

FIGURE 28.3. HD pathogenesis. The molecular chaperones (Hsp70 and Hsp40) promote the folding of newly synthesized htt into a native structure. Wild-type htt is predominantly cytoplasmic and probably functions in vesicle transport, cytoskeletal anchoring, clathrin-mediated endocytosis, neuronal transport or postsynaptic signaling. Htt may be transported into the nucleus and have a role in transcriptional regulation (1). Chaperones can facilitate the recognition of abnormal proteins, promoting either their refolding, or ubiquitination (Ub) and subsequent degradation by the 26S proteasome. The HD mutation induces conformational changes and is likely to cause the abnormal folding of htt, which, if not corrected by chaperones, leads to the accumulation of misfolded htt in the cytoplasm (2). Alternatively, mutant htt might also be proteolytically cleaved, giving rise to amino-terminal fragments that form β -sheet structures (3). Ultimately, toxicity might be elicited by mutant full-length htt or by cleaved N-terminal fragments, which may form soluble monomers, oligomers or large insoluble aggregates. In the cytoplasm, mutant forms of htt may impair the ubiquitin–proteasome system (UPS), leading to the accumulation of more proteins that are misfolded (4). These toxic proteins might also impair normal vesicle transport and clathrin-mediated endocytosis. Also, the presence of mutant htt could activate proapoptotic proteins directly or indirectly by mitochondrial damage, leading to greater cellular toxicity and other deleterious effects (5). In an effort to protect itself, the cell accumulates toxic fragments into ubiquitinated cytoplasmic perinuclear aggregates (6). In addition, mutant htt can be translocated into the nucleus to form nuclear inclusions, which may disrupt transcription and the UPS (7) [cited from Landles C and Bates GP. *Huntingtin and the molecular pathogenesis of Huntington's disease. Fourth in molecular medicine review series. EMBO Rep* 5, 958–63 (2004). Reprinted with permission from Nature Publishing Group].

Nuclear localization of htt fragments probably represents a downstream effect of proteolysis (Wellington and Hayden, 2003; Truant, 2003). Htt is a substrate for a number of proteases including caspases, calpains and aspartyl endopeptidases (Kim et al., 2001; Gafni and Ellerby, 2002; Wellington et al., 2002; Raymond, 2003; Wellington and Hayden, 2003), having 600 potential cleavage sites at the extreme amino terminal (Huntington's Disease Collaborative Research Group, 1993; Wellington and Hayden, 2003). Fragments of normal htt (including polyQ fragments of less than 29 repeats) are probably cleared by the ubiquitin-proteasome system. In contrast, the large expanded polyQ leads ultimately to cytoplasmic and nuclear aggregates (Verhoef et al., 2002; Ravikumar et al., 2003; Wellington et al., 2003).

28.7.3. Polyglutamine Tract/Htt Misfolding and Neurotoxicity

The toxic effect of HD polyglutamine tract has most often been studied within small N-terminal fragments of mutant htt (Beal et al., 1989; Davies et al., 1997; Di Figlia et al., 1997; Ravikumar et al., 2003; Raymond, 2003; Wellington and Hayden, 2003). However, the correlation of inclusions with cellular toxicity has been extremely variable, with some studies reporting toxic effects and others reporting protective effects (Bates and Hockly, 2003; Ross and Poirier, 2005). Both wild type and mutant htt fragments accumulate abnormally in the nucleus in HD brain and model systems early in the disease (Davies et al., 1997; Ross, 1997). Using various mouse model systems, it was shown that decreases in various mRNAs were due to an effect of the polyQ expansions, since it did not occur in transgenic mice carrying a normal polyQ tract (Mangiarini et al., 1996). This opened a number of potential pathways for HD-related pathologic changes and generated even more interest in HD brain and model systems transcription. Using microarray techniques and comparing changes in different transcriptional models and gene expression, at least some of the changes in transcription were found to be related to htt N-terminal fragments (Mangiarini et al., 1996; Steffan et al., 2000; Chan et al., 2002). In some of these strains, N-terminal fragments of mutant htt showed diminished expression of nerve growth factor receptor and deficits in neurite outgrowth (Li et al., 1999; Chan et al., 2002; Luthi-Carter et al., 2003). Changes were also noted in transcription factors in the cell models (Li et al., 1999; Luthi-Carter and Cha, 2003). There are interactions between htt and a number of polyglutamine-rich transcription factors as well as with transcription regulators (Nucifora et al., 2001; Luthi-Carter and Cha, 2003; Bae et al., 2005).

While soluble, mutant protein forms of htt can be degraded by proteasomes, the more stable insoluble aggregated forms tend to be more resistant (Verhoef et al., 2002; Ravikumar et al., 2003). In keeping with proteosomal resistance of aggregated mutant htt, its accumulation may

impair proteosomal function ultimately leading to cellular toxicity (Verhoef et al., 2002; Ravikumar et al., 2003) (Figure 28.3). Autophagy (process of bulk degradation of cytoplasmic proteins and damaged organelles) is probably the preferred route for clearance of aggregate-prone protein (Ravikumar et al., 2003). Increased endosomal-lysosomal-like organelles and vesicular bodies are seen in HD patients and transgenic mice (Ravikumar et al., 2003; Davies et al., 1997). The degradation of proteins by the ubiquitin-proteasome/autophagy-lysosome network does not affect nuclear protein since this system remains limited to the cytoplasm (Wellington and Hayden, 2003).

Proteosomal dysfunction leads to endoplasmic reticulum stress, which activates apoptotic signals, which in turn are activated by mutant polyQ expansions (Figure 28.3). Insulin growth factor-1 (IGF-1)/Akt pathway, as well as brain derived neurotrophic factor (BDNF), and ciliary neurotrophic factor (CNTF), block polyQ-htt-induced cell death (Humbert and Saudau, 2003; Saudou et al., 1998). IGF-1/Akt acts by phosphorylation of htt resulting in reduction of polyQ-htt-induced toxicity and thus is a potential therapeutic site. However, IGF-1/Akt activity induces cell proliferation, suggesting the need for a modified form (Humbert and Saudau, 2003). The data suggest that mutant polyQ Htt toxicity results from a series of events, some occurring simultaneously, leading to cell death in the targeted striatal neurons (Harper, 1996; Davies et al., 1997; Hayden and Leavitt 2000; Humbert and Saudau, 2003; Schilling and Borshelt, 2003; Truant, 2003; van Raamsdonk et al., 2005). Though the exact cause of cell death remains unclear, mitochondrial dysfunction must play a crucial role (Margolis and Ross, 2001; Ravikumar et al., 2003; Beal, 2005). A reasonable model was suggested with proteolysis initiating toxicity with production of N-terminal fragments of mutant htt and subsequent cascade of events in cytoplasm, nucleus and cell processes (Harper, 1996; Ross et al., 1998; Hayden and Leavitt, 2000; Margolis and Ross, 2001; Hersh, 2003; Raymond, 2003). These include initial proteolysis, followed by ubiquitination, autophagy, interruption of gene transcription and regulation, aggregate deposition, mitochondrial dysfunction, and further caspase activation leading to apoptotic cell death, occurring both sequentially and simultaneously (Ross et al., 1998; Margolis and Ross, 2001).

28.7.4. Htt Oligomer as Potential Pathogenic Form of HD Neurotoxicity

As described in the clinical course, neither the progression nor the duration of illness after neurological onset is strongly correlated with CAG length. The fact that the disease process triggered in HD is different from that triggered in other polyQ disorders indicates that some aspect of structure, binding partners, subcellular localization, or activity of htt is crucial to this specificity in neuropathology. As expression

of full-length mutant htt occurs throughout life and precedes the detection of N-terminal polyQ fragment in HD patients, it is possible that pathogenesis is triggered via novel property conferred on the htt protein. As an example, htt misfolding and oligomer formation triggered by the aggregation of the expanded polyQ has been proposed as a potential mechanism of htt dysfunction. This is supported by recent studies demonstrating the interaction of htt with a hetero-oligomeric chaperonin TriCcan prevents the aggregation and neurotoxicity of htt (Behrends et al., 2006; Tam et al., 2006). Short G-rich oligonucleotides, capable of adopting a G-quarted conformation, can also inhibit htt aggregation and neurotoxicity *in vitro* (Skogen et al., 2006). Thus, inhibition of htt misfolding may be a potential therapeutic venue for the treatment of HD in the future.

28.8. Glial Inflammation in HD

The neuroimmunological studies on HD are limited. However, PET imaging of HD gene carriers with a specific tracer for microglia, C-(R)-PK11195, specifically detected increased microglial accumulation in striatum in presymptomatic stage as compared to age-matched non-carrier controls (Tai et al., 2007). C-(R)-PK11195 is a radioligand for mitochondria peripheral benzodiazepine binding sites (PBBS), and its binding in striatum is also strongly correlated with severity in postsymptomatic HD stages (Pavese et al., 2006). Although this could reflect the microglial accumulation after the neuronal cell death in striatum for the clearance of damaged tissue, these report suggest that microglial accumulation can be used as a presymptomatic diagnosis of the disease for earlier treatment. In terms of immunotherapy on HD, preclinical studies have not been promising. NSAIDs, such as cerecoxib and refecoxib, have shown either no or detrimental effects on the transgenic mouse models of HD (Norflus et al., 2004; Schilling et al., 2004). Minocycline, an anti-inflammatory tetracycline analog extensively tested in multiple neurodegenerative disorder animal models, showed no effect on HD mouse models (Mievis et al., 2007). These studies suggest that glial inflammation can be monitored as one of the earliest sign of neurodegeneration, but may not be a likely target of HD treatment.

28.9. Preclinical Studies

Presently, trials involve an attempt to interrupt the pathways described above—proteolysis, caspase/calpain cleavage, nuclear entry, transcription disruption, growth factor receptor inhibition, mitochondrial dysfunction, ubiquitin and autophagy dysfunction, and aggregate disposition (Marx, 2005). Many of the trials include pre-symptomatic gene carriers, at-risk for the disease, demonstrating a need for reliable markers of disease progression. A full understanding of pathogenesis is

not necessarily required to begin therapeutic trials (Feigin and Zgalijardic, 2002; Hersh, 2003).

An understanding of the involved pathways outlined above provides multiple therapeutic targets. Interruption or alteration of these toxic pathways may slow the progression or delay the onset of clinical HD (McMurray, 2001). In transgenic animals various agents have been shown to inhibit caspases, depress aggregate formation, enhance normal cell functions, or combat oxidative stress (Rubinsztein, 2002). Glutamate receptor antagonists, antioxidants, and neurotrophic factors are examples of potential therapies to slow the course of HD. Altering dysfunction in one area may alter the course in other pathways since they are all interdependent to some extent (Marx, 2005).

Transgenic animals, cell systems, and micro array techniques demonstrate a large number of potential agents for human trials. Some of these have already been tested in humans with mixed results—riluzole, coenzyme Q10, remacemide, minocycline, and 10-ethyl-10-deaza-aminopterin (Schilling and Borshelt, 2003; Feigin et al., 2006). Compounds in ongoing trials include: creatine (an endogenous substrate for creatine kinases) (Tabrizi et al., 2005), cystamine (decreases transglutaminase activity) (Hersh, 2003; Schilling and Borshelt, 2003), amantidine (a noncompetitive NMDAR antagonist) (Hersh, 2003), memantine (an NMDA receptor antagonist) (Beister et al., 2004), clioquinol (a metal-binding compound) (Nguyen et al., 2005), rapamycin (an autophagy inducer) (Berger et al., 2006), and Congo red (protein aggregation inhibitor). Neurotrophic factors (BDNF) and IV infusion of stem cells are among others (Feigin and Zgalijardic, 2002; Bates and Hockly, 2003; Hersh, 2003; Schilling and Borshelt, 2003; Lee et al., 2005). Other candidate compounds include: interleukin-6, adenosine A2A antagonists, dichloroacetate, lipoic acid, lithium and celestrol (Margolis and Ross, 2001; Feigin and Zgalijardic, 2002; Bates and Hockly, 2003; Hersh, 2003; Schilling and Borshelt, 2003).

Summary

Huntington's disease is an autosomal dominant neurological disorder involving the expansion of polyglutamine tract. However, the genetic evidence has indicated that the initial triggering event in the HD pathogenic process occurs at the level of the full-length protein rather than small fragments which appear only later in the disorder. This triggers progressive alterations in cell function that occurs simultaneously, including aggregation of mutant protein in both cytoplasm and nucleus. Following discovery of the mutant gene in 1983, relatively rapid progress has been made with the advent of promising pharmacotherapy to alter disease progression. Though the exact pathogenesis remains unknown, a number of pathologic pathways have been investigated revealing multiple potential therapeutic targets that may alter the course of HD, or delay its onset.

Review Questions/Problems

1. Huntington's disease is a familial and rare inherited neurological disorder affecting up to:

- 8 people per 100,000
- 1 per 20,000 people of Western European decent
- 1 per one million in people of Asian and African descent
- All of the above

2. What is true about the national history and epidemiology of HD?

- Men are affected more than woman.
- It is an inherited genetic disorder where an accurate test is not available.
- Description of the disease complex was ascribed to Frederick Huntington in 1972.
- All of the above.
- None of the above

3. The following is known about the pathogenesis of HD

- The genetic mutation that causes HD was discovered in 1993.
- The mechanism by which mutant Htt causes neuronal dysfunction is well known.
- Excitotoxicity has been proposed as a pathogenic mechanism, on the basis of the observation that infusion of glutamate-receptor agonists into the brain leads to neuronal death and a phenotype similar to HD.
- Mitochondrial dysfunction is another leading hypothesis for HAD pathogenesis
- All of the above
- a, c and d only

4. The genetic defect responsible for HD is

- A small sequence of DNA on chromosome 4 in which several base pairs are repeated many, many times.
- The normal gene has three DNA bases, composed of the sequence CAG.
- In people with HD, the sequence abnormally repeats itself dozens of times.
- Over time—and with each successive generations—the number of CAG diminishes.
- All and above
- a, b, and c only

5. HD involves all ethnic groups and is most frequent in patients of Caucasian descent.

True/False

6. The hallmark of HD pathology is the regional atrophy and neuronal loss in the brain stem.

True/False

7. A triad of major clinical finding characterizes disease: abnormal involuntary movements, personality/behavioral disorders, and cognitive deterioration.

True/False

8. Ocular, orofacial and speech abnormalities are not part of the HD disease complex.

True/False

Prion Diseases

Qingzhong Kong and Richard A. Bessen

Keywords Creutzfeldt Jakob disease; Fatal insomnia; Gerstmann-Straussler-Scheinker; Kuru; Neuroinvasion; Prion; Protein-only hypothesis.

29.1. Introduction and History of Prion Diseases

The modern history of the prion diseases is one of novel microbes, anthropological intrigue, and food safety mishaps. The prion diseases, also called the transmissible spongiform encephalopathies, are fatal neurodegenerative diseases that can be sporadic, inherited, or acquired. These multiple origins are unique among human disease. The basis of all prion diseases is the misfolding of the host prion protein into the disease-specific prion protein conformation, called PrP^{Sc}. Transmission of PrP^{Sc} into naïve hosts can lead to additional prion protein misfolding and induction of neurodegenerative disease. Hence, prion diseases are transmissible but are caused by a novel pathogen that lacks a prion-specific nucleic acid genome.

In the 1950s Carleton Gajdusek, an American physician, was attracted to the highlands of New Guinea by reports of a mysterious condition called kuru that was ravaging the Fore stone-age tribes. Kuru primarily afflicts woman and young children and victims succumb to neurological illness that includes shivering and twitching but rapidly progresses to ataxia, paralysis, and eventually death. Gajdusek was perplexed as to the cause of kuru and it was the observation of William Hadlow, a veterinary pathologist, which led to the recognition of the human prion diseases. Hadlow observed the striking similarity in neuropathology between scrapie, a transmissible disease in sheep, and kuru and reasoned that if kuru and scrapie are similar diseases, then kuru should be transmissible to non-human primates (Hadlow, 1959). Gajdusek inoculated kuru into chimpanzees and transmitted neurological disease (Gajdusek et al., 1966). Once the infectious etiology of kuru was established, transmission of kuru was linked to ritualistic endocannibalism among the Fore people. Shortly afterwards,

Gajdusek reported transmission of sporadic Creutzfeldt-Jakob disease (CJD), a neurological disease first described in the 1920s, to chimpanzees and they developed neuropathology characteristic of the prion diseases, which includes neuronal loss, spongiform changes, and astrogliosis. These pioneering studies established that kuru and CJD, which were thought to be unrelated diseases of unknown etiology, belong to the same group of human transmissible spongiform encephalopathies. Gajdusek received the Nobel Prize in Physiology or Medicine in 1976 for his work on human prion diseases.

Although the human and animal prion diseases were known to be transmitted by an infectious agent, the unusual resistance of these agents to chemical and physical inactivation was perplexing and led to theories that they were caused by an unconventional slow virus. In 1982, Stanley Prusiner reported that scrapie in sheep was caused by prions, which were defined as infectious proteinaceous particles that are devoid of a nucleic acid (Prusiner, 1982). This hypothesis was met with immense skepticism from the scientific community since it challenged the central principle of molecular biology that genetic information flows from DNA to RNA to protein. However, Prusiner, and others, were able to build upon this theory and his pioneering work was also recognized with a Nobel Prize in Physiology or Medicine in 1997.

Another bizarre chapter in prion diseases began in the mid-1980s with the identification of bovine spongiform encephalopathy (BSE) in cattle. This prion disease was transmitted by industrial cannibalism in which livestock feed was supplemented with meat and bone meal that was unknowingly derived from prion-infected sources, most likely from scrapie-infected sheep. BSE peaked at over 35,000 cases a year in the United Kingdom in the early 1990s but the prevalence has been greatly reduced by the removal of ruminant-derived protein sources in livestock feed. However, the BSE agent is a highly pathogenic strain of prion and is the causative agent for a new human prion disease called variant CJD (Will et al., 1996).

The human prion diseases include CJD, kuru, Gerstmann-Straussler-Scheinker (GSS), and fatal insomnia, which can be classified into three groups based on etiology (Table 29.1).

TABLE 29.1. Origin and prevalence of the human prion diseases.

Human prion disease (percent)	Prevalence	Origin (Distribution)
Sporadic (85–90%)		
Creutzfeldt- Jakob Disease	1 in 10 ⁶ per year	Spontaneous (worldwide)
Fatal insomnia	9 cases	Spontaneous
Familial (10–15%)		
Creutzfeldt-Jakob disease E200K-129M	3–5%*	Germ line mutation in <i>PRNP</i>
All other families	97 families	Germ line mutations/ insertions in <i>PRNP</i>
Fatal familial insomnia	30 families	Germ line mutation in <i>PRNP</i>
Gerstmann-Straussler- Scheinker	72 families	Germ line mutations/ insertions in <i>PRNP</i>
Acquired (~1%)		
Variant CJD	200 cases	BSE infection (UK, Europe)
Iatrogenic CJD	405 cases	Medical practices (France, Japan, US)
Kuru	~2700 cases	Cannibalism (Papua New Guinea)

* Percent of all human prion diseases based upon epidemiological data from Italy and Japan.

29.2. Prion Protein Gene and Gene Products

29.2.1. Prion Protein Gene and PrP^C

The prion protein is a normal cellular membrane protein that is expressed at high levels in the nervous system, testis, muscle, some hemapoetic cells, and follicular dendritic cells (reviewed by Makrinou et al., 2002). In humans the prion protein is encoded by a single copy gene, which is called *PRNP* and is located on chromosome 20. As illustrated in Figure 29.1A, *PRNP* has two exons and a single intron that span about 15 kb; exon 2 contains the prion protein coding sequence (reviewed by Makrinou et al., 2002). In the *PRNP* coding region there are a large number of pathogenic mutations that are linked to, or have been associated with, the familial prion diseases (Figure 29.1B) (reviewed by Kong et al., 2003). Polymorphisms are also present and the one at codon 129 (methionine or valine) plays an important role in determining susceptibility, clinical phenotype or disease duration in the prion diseases.

The cellular form of the prion protein, called PrP^C, is synthesized as a 253 amino acid precursor protein in humans (Figure 29.1B) (Prusiner, 1991). The N-terminal 22 amino acid residues serve as the signal peptide that allows insertion of the nascent PrP^C peptide into the secretory pathway during biosynthesis. The C-terminal 22 amino acid residues are involved in the covalent addition of the glycosylphosphatidylinositol (GPI) moiety to serine at amino acid 231 (i.e., Ser²³¹). The GPI anchor tethers PrP^C to the extracellular side of the plasma membrane. PrP^C has two N-linked glycosylation sites (Asn¹⁸¹ and Asn¹⁹⁷) that are the sites of attachment of complex

carbohydrates. There are three major PrP^C glycoforms that are defined by the number of N-linked carbohydrate moieties; these are referred to as diglycosylated, monoglycosylated, and nonglycosylated forms (Figure 29.2). The N-terminal region of PrP^C has five octapeptide repeats that bind metal ions (e.g., copper, zinc) but the structure of this domain is undefined, while the C-terminal portion consists of three α -helical and two short β -sheet domains (Figure 29.1B). The cellular function(s) of PrP^C is diverse and it has been implicated in neurogenesis and differentiation (Steele et al., 2006), hematopoietic stem cell self renewal (Zhang et al., 2006), metal ion transportation (Wong et al., 2001), antioxidant activity, signal transduction, apoptosis, and sleep regulation (Tobler et al., 1996; Lasmezas, 2003).

29.2.2. The Protein-Only Hypothesis for the Prion Diseases

Identification of the infectious agent causing prion diseases has been controversial due to its small size and resistance to procedures that inactivate most microorganisms as well as nucleic acids. Extensive efforts to detect a prion-specific small virus or nucleic acid genome have been unsuccessful (Safar et al., 2005). In contrast, procedures that destroy proteins also inactivate prion infectivity. Despite much debate, it is generally agreed that prion diseases are caused by prions, which are defined as proteinaceous infectious particles that lack a nucleic acid genome (Prusiner, 1991). The protein-only hypothesis states that the infectious agent is a misfolded form of PrP^C that is called PrP^{Sc}, the “Sc” refers to scrapie. PrP^{Sc} has distinct biochemical properties from PrP^C that include partial resistance to degradation by proteolytic enzymes, insolubility in detergents, and aggregation into linear fibrils. The basis for these unusual features of PrP^{Sc} is a conformational conversion of α -helical to β -sheet conformation. Replication of the prion agent has been postulated to occur by a protein self-assembly mechanism by which the abnormal PrP^{Sc} fibril can convert the monomeric PrP^C into a subunit of the growing PrP^{Sc} fibril (Jarrett and Lansbury, 1993).

Although the scientific community was initially skeptical of the prion hypothesis, in the past twenty years several key experiments have demonstrated support for this novel concept. PrP null mice, in which the endogenous prion protein gene has been removed, do not demonstrate the ability to produce PrP^{Sc} and prion infectivity nor do they develop prion disease when inoculated with the scrapie agent (Sailer et al., 1994). Additional studies used transgenic mouse models in which the prion protein transgene corresponds to a mutation common in Gerstmann-Straussler-Scheinker disease (GSS), a proline to leucine mutation at codon 102 (i.e., P102L). These transgenic P102L mice spontaneously develop prion disease and the neuropathology is characterized by PrP^{Sc} amyloid plaques, which are similar to plaques found in GSS patients (Hsiao et al., 1990). This classic study demonstrated that mutations in *PRNP* are directly linked to the human prion diseases. Another

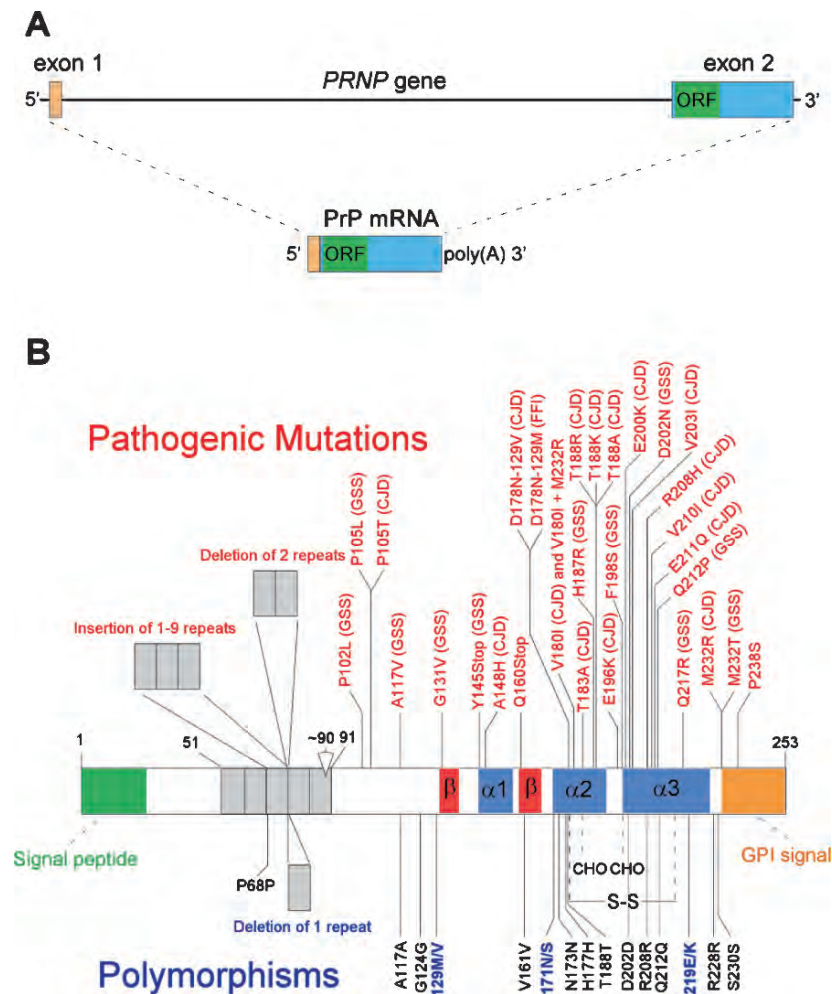

FIGURE 29.1. Diagram of the *PRNP* gene and the PrP protein. (A) The prion protein gene and mRNA. The PrP ORF is located within exon 2 and is highlighted in green. (B) The PrP protein linear map with posttranslational modifications, polymorphisms, and pathogenic mutations (modified from Figure 29.2 in Kong et al. 2003). The numbers indicate the amino acid residue position in the prion protein and the single letter designation for amino acids is used to denote polymorphisms and mutations. The signal peptides at the amino and carboxyl terminus are indicated in green and orange, respectively. The octapeptide repeats are indicated by grey boxes, while the three α -helices and two short β -sheets are indicated by pale blue and red boxes, respectively. Mutations linked to the human prion diseases are illustrated in red type above the PrP map while normal polymorphisms are indicated below. The arrowhead at amino acid 90 indicates the major cleavage site for proteinase K, which degrades the N-terminal portion of PrP^{Sc}. The two N-linked carbohydrate groups (CHO) and disulfide linkage (-S-S-) are also illustrated.

important proof of the prion hypothesis was the *in vitro* production of prion infectivity following conversion of noninfectious recombinant mouse PrP^C into an aggregated fibrillar complex that has a rich β -sheet conformation (Legname et al., 2004).

29.2.3. Molecular Classification of PrP^{Sc} in Human Prion Diseases

Biochemical characterization of PrP^{Sc} reveals heterogeneity in the polypeptide patterns among the human prion diseases and this has been useful for the molecular classification of PrP^{Sc} (reviewed by Gambetti et al., 2003). Limited proteinase K

digestion of PrP^{Sc} removes a ~7 kDa N-terminal fragment but leaves intact a protease-resistant PrP^{Sc} core. Typically, there are three protease-resistant polypeptide fragments, referred to as glycoforms, which differ in molecular weight by the addition of zero, one, or two N-linked carbohydrate groups (Figure 29.2). Among the human prion diseases, PrP^{Sc} polypeptide fragments can vary in number (typically 1 to 3), molecular weight, and the ratio of the three glycoforms. Based on these criteria, PrP^{Sc} is classified into three operational groups called type 1, type 2 (a and b), and GSS-type (Table 29.2, Figure 29.2). Type 1 PrP^{Sc} is found in the majority of sporadic CJD (sCJD) cases, some familial CJD (fCJD) cases, and at small

FIGURE 29.2. Schematic diagram of PrP^{Sc} types found in human prion diseases. The three major prion protein polypeptide glycoforms are illustrated on SDS-PAGE (lane 1). The relative amount of each PrP polypeptide in relation to the other glycoforms is indicated by the shading intensity of each band. The molecular weight of the major nonglycosylated PrP^{Sc} polypeptide band is indicated in kilodaltons (kDa). PrP^{Sc} types are defined after limited digestion with proteinase K (PK), which removes the N-terminal portion of the prion protein (lanes 2 to 5). PrP^{Sc} subtypes are defined by the molecular weight of the nonglycosylated PrP^{Sc} polypeptide and the ratio of the three PrP^{Sc} glycoforms. This is one criterion that is used for the molecular classification of the human prion diseases. In type 1 PrP^{Sc} there is an additional 12-13 kDa polypeptide.

TABLE 29.2. Classification of PrP^{Sc} types in human prion diseases.

PrP ^{Sc} Type*	N-terminus, amino acid	C-terminus, amino acid	Nonglycosylated PrP ^{Sc} , kDa
Type 1	~82	231	~21
Type 2	~97	231	~19
GSS-type	74–90	147–153	7–8

* After limited proteolytic digestion with proteinase K.

amounts in all CJD cases (Yull et al., 2006). The type 2a PrP^{Sc} is associated with a minority of sCJD cases, sporadic fatal insomnia (sFI) and some fCJD cases. Many sCJD patients (20% or more) possess both type 1 and type 2 PrP^{Sc}. In vCJD, PrP^{Sc} polypeptides have a similar molecular weight as found in type 2a PrP^{Sc} but the ratio of the three PrP^{Sc} glycoforms are different. Therefore, vCJD is referred to as type 2b PrP^{Sc} (Figure 29.2). In GSS, a 7–8 kDa PrP^{Sc} polypeptide is referred to as GSS-type PrP^{Sc} and it is only found in GSS cases.

29.3. Epidemiology and Clinical Features of Human Prion Diseases

The human prion diseases are rare but fatal neurodegenerative diseases that have long incubation periods ranging from years to decades. The clinical course is progressive and exhibits a complex neurological pattern that also can last from months to years. Presenting symptoms vary depending on the type of human prion disease, but most will display cognitive, motor, and behavioral deficits during the clinical phase. Some of the prion diseases target to specific brain regions while others have a widespread distribution in the brain. The incubation

time, age at onset of clinical symptoms, and disease duration is variable among the human prion diseases and there is often overlap in these features among the major types of human prion diseases (Table 29.1).

29.3.1. Sporadic Human Prion Diseases

Sporadic CJD is the most common human prion disease and accounts for 85–90% of all human cases (reviewed by Gambetti et al., 2003). Sporadic prion diseases are associated with type 1, type 2a (sCJD), or a mixture of type 1 and type 2 PrP^{Sc}. sCJD can be further classified into five subtypes based on a combination of molecular, clinical and pathological features including 1) the genotype at codon 129 of *PRNP* (Methionine or Valine) and 2) the type of protease resistant PrP^{Sc} fragments (1 or 2). These subtypes are designated sCJDM1/sCJDMV1, sCJDM2, sCJDVV1, sCJDVV2, and sCJDMV2. These five subtypes of sCJD are associated with distinct clinical and/or pathological characteristics (Parchi et al., 1999; reviewed by Gambetti et al., 2003). In addition to clinical symptoms, periodic sharp wave (PSW) complexes on electroencephalogram (EEG), MRI (hyperintense signal), and the presence of 14–3–3 protein in cerebral spinal fluid (CSF) are useful diagnostic markers for CJD.

The sCJDM1/sCJDMV1 subtype displays either MM or MV at PrP codon 129 and type 1 PrP^{Sc}. It is the most common subtype and accounts for 60–70% of all sporadic human prion disease. This sCJD subtype has a mean age at clinical onset of 65 years of age and the mean duration of clinical symptoms prior to death is approximately four months. The symptoms at clinical presentation can include cognitive impairment, widened gait or ataxia, behavioral signs (including depression, anxiety,

psychosis), and vision defects. Myoclonus and pyramidal signs develop at later stages of clinical disease. PSW complexes on EEG are present in the majority (~80%) of subjects within three months of clinical onset. Protein 14–3–3 in CSF is found in 95% of cases. Therefore, concurrent PSW and 14–3–3 positive CSF are often used as a diagnostic marker for sCJD.

The sCJDVV2 subtype has a VV at PrP codon 129 and type 2 PrP^{Sc}. It is the second most common form of sCJD and accounts for ~16% of all sporadic human prion disease. The mean age at onset is 60 years and the mean duration of the clinical phase is six months. Ataxia is the most common presenting symptom for this subtype. At later stages, dementia almost always develops and is accompanied by myoclonus and pyramidal signs. PSW on EEG is rare and CSF 14–3–3 is positive in ~80% of cases.

The sCJDMV2 subtype has MV at PrP codon 129 and type 2 PrP^{Sc}, and it represents ~9% of the sporadic cases. This subtype has a phenotype very similar to that of sCJDVV2 except for a longer clinical phase before death (mean of 17 months), greater involvement of cognitive and mental symptoms at earlier stages, and frequent aphasia and apraxia at later stages.

The sCJDMM2 subtype has MM at PrP codon 129 and type 2 PrP^{Sc}, and it accounts for 2–8% of the sporadic cases. The mean age at onset is 65 years and the mean clinical duration is 16 months. Cognitive impairment is the universal presenting symptom and is sometimes accompanied by aphasia. At later stages, myoclonus and pyramidal signs, and sometimes Parkinsonism, apraxia, and seizures, develop. There is no PSW on EEG while CSF 14–3–3 is positive in most cases.

The sCJDVV1 subtype has VV at PrP codon 129 and type 1 PrP^{Sc}, and it accounts for 1% of the sporadic cases. The mean age at onset is 39 years and the mean clinical duration is 15 months. This younger age of clinical onset is unusual for a sporadic human prion disease and more closely resembles the age of onset that is characteristic in vCJD. This subtype shows dementia at the early clinical stages and is followed by myoclonus and pyramidal signs. There is no PSW on EEG and the CSF 14–3–3 is positive in all cases tested.

In sporadic fatal insomnia (sFI) there is MM at PrP codon 129 and type 2 PrP^{Sc}. sFI accounts for ~2% of the sporadic cases and the phenotype is similar to that of inheritable FFI, which is characterized by insomnia, but visual signs, cognitive impairment, and motor signs are also common. The mean age at onset is 50 years with a mean clinical duration of 24 months.

29.3.2. Familial Human Prion Diseases

The familial prion diseases are inherited in an autosomal dominant manner and account for 10–15% of all human prion disease. They include familial CJD (fCJD), GSS, and fatal familial insomnia (FFI) (reviewed by Gambetti et al., 2003 and by Kong et al., 2003). The familial prion diseases are caused by pathogenic mutations in the *PRNP* coding sequence. To date, these include 24 mis-sense mutations that result in amino

acid changes, 2 nonsense mutations that result in premature stop codons, and about 30 insertion or deletions that lead to changes in the octapeptide repeat number (Figure 29.1B). There are 16 polymorphic sites in *PRNP* (Figure 29.1B). The most important polymorphism is at codon 129, which affects the clinical symptoms in *cis* to the mutant allele and modifies the age of onset and disease duration in *trans* to the mutant allele (reviewed by Kong et al., 2003).

There are eleven mutations in *PRNP* that have been linked to fCJD and these include D187N, V180I, T183A, T188A, E196K, E200K, V203I, H208R, V210I, E211Q, and M232R (Figure 29.1B). In fCJD the disease phenotype is often similar to that found in sCJD, but there can be heterogeneity between individuals carrying different or even the same *PRNP* mutation. This is illustrated in the most common fCJD cases, which is caused by an E200K amino acid substitution in the prion protein. Some individuals with the E200K genotype have a methionine at codon 129 on the mutant allele (i.e., fCJD^{E200K-129M}) and a type 1 PrP^{Sc}, while others with the same E200K mutation have a valine at codon 129 (i.e., fCJD^{E200K-129V}) and a type 2 PrP^{Sc}. In fCJD^{E200K-129M}, the mean age at onset is 58 years and the average clinical duration is 6 months. Symptoms at clinical onset include cognitive and mental impairment that is often accompanied by cerebellar signs and sometimes by visual symptoms and myoclonus. Later in the disease course, seizures and motor and sensory peripheral neuropathy can also be present. These later signs are rare in sCJD. There is PSW on EEG and CSF 14–3–3 is also positive in the majority of affected subjects. In contrast, fCJD^{E200K-129V} individuals have a phenotype similar to that of sCJDVV2, which presents primarily as ataxia followed by myoclonus with PSW on EEG at late stages. This phenotypic difference between fCJD^{E200K-129V} and fCJD^{E200K-129M} illustrates the dramatic influence of the codon 129 polymorphisms on disease phenotype and PrP^{Sc} type. Other common fCJD mutations include D178N-129V and V210I-129M or insertions of one to four octapeptide repeats.

GSS is an inheritable prion disease characterized by PrP^{Sc} deposits in the form of amyloid plaques in the cerebral cortex, degeneration of pyramidal tracts, and a long clinical duration. In GSS there is a highly variable age at onset (between 20 and 73 years) and duration of the clinical phase (mean of 5 years, but range between 5 months and 21 years). The symptoms usually include a slowly progressive cerebellar syndrome, pyramidal signs, and cognitive decline that often develop into dementia. GSS could be mistaken for other common neurodegenerative diseases due to the similarity in clinical signs. These include olivopontocerebellar atrophy, spinocerebellar ataxia, Parkinson disease, amyotrophic lateral sclerosis, Huntington's disease, and Alzheimer disease (Kong et al., 2003). Mutations in *PRNP* that have been linked to GSS include P102L, P105L, A117V, G131V, Y145stop, H187R, F198S, D202N, Q212P, Q217R, and M232T.

PrP^{P102L-129M} is the most common GSS genotype and is the first reported *PRNP* mutation linked to human prion dis-

ease. It has been reported in at least 28 families around the world and it may have occurred independently more than a single time since it is detected in families of different ethnicity. In GSS^{P102L-129M}, a protease-resistant PrP^{Sc} polypeptide of 7–8 kDa is the major component of amyloid plaques in the brain. The age at onset is between 30 and 63 years with clinical duration of 1 to 10 years. However, some subjects have a CJD-like phenotype accompanied by a short clinical duration of 5 to 9 months. The initial symptoms include progressive cerebellar signs with ataxia, dysarthria, incoordination of saccadic movements, and occasional pyramidal and pseudo-bulbar signs. Dementia and akinetic mutism develop at late stages of the disease. Polymorphic variants of the PrP^{P102L-129M} allele include PrP^{P102L-129V} and PrP^{P102L-129M-219K} and these have distinct disease phenotypes.

Fatal familial insomnia is the second most common inherited prion disease and is associated with a D178N-129M mutant allele (reviewed by Kong et al., 2003 and by Montagna et al., 2003). The average age at onset is 49 years but can vary between 20 and 72 years. The duration of the clinical phase also is highly variable with an average of 11 months for 129MM subjects and 23 months for 129MV subjects. Severe insomnia is the most prominent symptom and is likely due to prion targeting to the thalamus, which is reflected in abnormal brain activities in this region on PET and SPECT scans. Other symptoms can include episodes of hallucinations and confusion, myoclonus, spasticity, and seizures. EEG is usually slowed and PSW complexes are often present in patients with long duration. There is a characteristic shortened sleep time and irregular transition between sleep stages on polysomnography. The same D178N mutation is found in fCJD but these individuals have a 129V genotype on the mutant allele and, as a result, the disease phenotype is different and does not include insomnia.

29.3.3. Acquired Human Prion Diseases

The acquired prion diseases account for less than 1% of all human prion disease cases and these include variant CJD, iatrogenic CJD (iCJD), and kuru (reviewed by Will, 2003). In these cases, prion infection is either orally acquired or associated with accidental transmission via medical practices. Many of these latter cases involve contamination with brain tissue, which contains the highest amount of prion infectivity, from the donor host.

Variant CJD was discovered in 1996 and is most likely due to ingestion of BSE-contaminated food products, but direct proof is lacking due to the long interval between exposure and onset of disease. Removal of meat and bone meal supplements from livestock feed in the late 1980s has greatly reduced the prevalence of BSE in the United Kingdom from over 35,000 cases in 1992 to less than 1,000 cases in 2005. As a result, human exposure to BSE has also been greatly reduced. To date, there are 200 cases of vCJD primarily in the United Kingdom. The annual number of vCJD cases reached a peak at 28 in 1999, but this number of cases is relatively low considering that

approximately 1,000,000 BSE-infected cattle have entered the human food chain in the UK during the 1980s and 1990s. Due to the long prion incubation period, it is difficult to predict the size of the vCJD epidemic. A retrospective survey of tonsils and appendix specimens (i.e., sites of prion agent replication) removed during routine surgery in the UK revealed only three PrP^{Sc} positive samples in >18,000 cases (Hilton et al., 2004). This suggests that there is no large number of individuals with subclinical vCJD infection as originally estimated. Predictive models currently place the upper number of vCJD cases at 451 by 2010 (Cooper and Bird, 2003).

The clinical and pathological phenotype of vCJD is distinct from most of the other human prion diseases and these unusual features were important in the identification of vCJD (reviewed by Ironside et al., 2005). Unlike the common sporadic forms of human prion disease that primarily afflict individuals in their sixth decade, vCJD is found in younger individuals with mean age of onset at 28 years, ranging between 12 and 74 years of age (reviewed by Will, 2003). The length of the incubation period is uncertain but is estimated to be ~11 years (Cooper and Bird, 2003). The mean clinical duration is ~14 months, which is longer than the 4 months for sCJDMM1 but comparable to that of 16 months for sCJDMM2. All clinical vCJD subjects had PrP^{129MM}. The PrP^{129MM} genotype has a prevalence of 39% in the UK population so the higher distribution in vCJD cases indicates a stronger preference for younger people with a PrP^{129MM} genotype. There could be an age-related exposure or age-dependence for vCJD but none has been demonstrated. The type 2B PrP^{Sc} is characteristic of vCJD (Table 29.2, Figure 29.2) and PrP^{Sc} deposits are present in florid amyloid plaques in the brain. In contrast to the diverse clinical symptoms among sCJD cases, the symptoms of vCJD subjects are more uniform. The presenting symptoms include psychiatric signs and occasionally neurological symptoms (persistent pain, memory impairment). After about 6 months, signs of ataxia, cognitive impairment, and involuntary movements become apparent. Bilateral pulvinar high signal in the thalamus on MRI is prominent in the majority of cases (~78%) (Zeidler et al., 2000). There is general slowing but no PSW complexes on EEG.

Iatrogenic CJD is the second most common acquired human prion disease and these cases are the result of accidental infection due to contact with prion contaminated tissues or instruments during medical procedures (Table 29.1). The mode of prion infection include surgical equipment (e.g., surgical instruments, depth electrodes), transplantation of human tissues (corneal, dura mater), intramuscular injections with growth hormone or gonadotrophin extracted from human pituitary tissues, or blood transfusion (reviewed by Will, 2003). The most likely source of infection is from donors with subclinical sCJD, except for the two transfusion-related cases that have been linked to blood donors who developed vCJD several years later (reviewed by Ironside, 2006). The incubation period in these transfusion related cases was 5 to 6 years, which is shorter than primary vCJD infection in humans.

The most common cases of iCJD are in recipients of human growth hormone therapy that is used to treat children with growth deficits (reviewed by Will, 2003). There have been over 194 cases reported worldwide and these have been linked to growth hormone extracted from cadaveric pituitaries. The clinical and pathological features of growth hormone therapy-related iCJD are distinct from sCJD. The mean incubation period is 12 years (range between 4.5 and 38 years) and the presenting symptoms include progressive cerebellar signs that are sometimes followed by dementia at later stages. The second most common iCJD cases are found in recipients of dura mater homograft (at least 190 cases). Afflicted individuals show typical sCJD symptoms with an incubation period of ~6 years (range between 1.5 and 18 years).

Kuru is an acquired human prion disease of indigenous tribes in Papua New Guinea that is linked to ritualistic endocannibalism (Alpers, 1979). More than 2700 cases have been recorded since the 1950s, but this disease has gradually disappeared since the cessation of cannibalism in the late 1950s. The mean incubation period for kuru is about 12 years, but the longest on record is over 50 years. The clinical duration is 6 to 36 months in adults and the main presenting symptom is cerebellar signs, which are often followed by severe dysarthria at late stages in the absence of dementia.

29.4. Neuropathology of Human Prion Diseases

The three principal neuropathological features in human prion diseases are neuronal loss, gliosis, and spongiform changes primarily in grey matter (reviewed by Mikol, 1999). There is considerable diversity among the human prion diseases with respect to the location of pathology in the brain and type of neurons affected. Pathology is not confined to a single brain structure but is widely distributed in the CNS. For each of the human prion diseases, there are typical distinguishing features of neuropathology that are partially defined by the distribution of pathology in the cerebral cortex, subcortical grey matter, and brainstem. Spongiform changes can vary in density and size and range from microvacuolation to the fusion of vacuoles to produce status spongiosis. The degree of spongiform change does not appear to correlate with neuronal loss. Amyloid plaques are also present in the brain in some of the human prion diseases, most notably kuru, vCJD and GSS. These amyloid plaques exhibit birefringence when stained with Congo red and viewed under polarized light.

PrP^{Sc} deposition in the central nervous system is also a hallmark feature of prion disease (Prusiner, 1991). The type of PrP^{Sc} deposit and its location varies among the human prion diseases. PrP^{Sc} is also a component of amyloid plaques. A characteristic of vCJD and kuru is florid amyloid plaques, which is a large cluster of PrP^{Sc} aggregates interspersed with vacuolar pathology. PrP^{Sc} deposition is also present in peripheral tissues of patients with vCJD, primarily in secondary

lymphoid tissues. However, no histological changes are apparent in peripheral organs of prion-infected hosts.

In prion diseases, there is a notable absence of encephalitis. The lack of adaptive immune response to PrP^{Sc} is likely due to host tolerance to PrP^C. However, there is an increase in the numbers of microglia, activation of astrocytes, upregulation of proinflammatory cytokines, binding of C1q and C3b components to PrP^{Sc}, and complement membrane attack complexes associated with neurons in the brain (Burwinkel et al., 2004; Kovacs et al., 2004; Mabbott, 2004). The precise role of these host responses in neuroprotection and/or neurodegeneration during prion infection is not clear. Interestingly, mice that lack interleukin-10, an anti-inflammatory cytokine, are more susceptible to experimental prion disease (Thackray et al., 2004). In the brains of these mice, there was faster upregulation of pro-inflammatory cytokines (e.g., TNF- α and IL-1 β) suggesting that inflammation may be a central event in prion-induced neurodegeneration.

The neuropathology among sCJD cases is not uniform and is variable in nature, severity and location in the brain. In most cases spongiform change is found in the cerebral cortex, cerebellar cortex, and/or the subcortical grey matter (reviewed by Ironside et al., 2005). This is accompanied by reactive gliosis and neuronal loss but there is not a consistent relationship between spongiform change and cell loss. In approximately 10% of sCJD, PrP^{Sc} amyloid plaques are present in the cerebral cortex but most cases have a diffuse synaptic PrP^{Sc} distribution. In contrast to the clinical and pathological diversity present in sCJD, the pathology in vCJD is more uniform. The central pathological features in vCJD are the presence of florid PrP^{Sc} plaques in the cerebral and cerebellar cortex, severe spongiform change in the caudate and putamen, and neuronal loss in the thalamus and midbrain. PrP^{Sc} is also present in affected brain regions. The neuropathology of vCJD is distinct from the other human prion diseases.

In the familial human prion diseases there are also variable clinical and neuropathological features. GSS is characterized by unicentric and multicentric PrP^{Sc} amyloid plaques that are primarily found in the cerebellum, but can also be present in the cerebral cortex (reviewed by Ghetti et al., 1995). Spongiform change and neuronal loss can be focal but some GSS patients have no spongiform changes, while in other cases with a short duration, there is widespread spongiform change. In some GSS families, severe neurofibrillary tangle degeneration is prominent. A feature of FFI is a thalamic degeneration characterized by severe spongiform change, neuronal loss, and astrocytosis in thalamic nuclei (reviewed by Gambetti et al., 1995).

29.5. Peripheral Prion Replication and Neuroinvasion

The sites of prion agent replication and spread are largely dictated by whether the etiology of prion disease is sporadic, familial, or acquired. For example, in sCJD and fCJD, disease initiates in, and is largely confined to, the nervous system. In

vCJD, which is acquired via oral ingestion, infection likely begins in secondary lymphoid tissues prior to neuroinvasion and spread to the CNS.

29.5.1. vCJD and Oral Routes of Animal Prion Transmission

Variant CJD is BSE infection in humans and the most probable route of infection is by ingestion of BSE-contaminated food products. The spread of the vCJD agent following oral ingestion has not been directly investigated but evidence suggests it follows a similar pathway to that described for oral ingestion in the animal prion diseases. These pathways have been well described for scrapie in sheep and in rodent models and have three phases: agent entry and replication in secondary lymphoid tissues, spread from secondary lymphoid tissues to the CNS along peripheral nerves, and dissemination and degeneration in the CNS (Figure 29.3). Following oral prion ingestion, the prion agent is initially found in the distal ileum (Heggebo et al., 2000). Entry is likely across the intestinal epithelium via the M cells in the Peyer's patches. Prions then spread to the draining gut-associated lymphoid tissue (GALT) where prion agent is found within months after ingestion (van Keulen et al., 1999). In the GALT, the prion agent is primarily associated with follicular dendritic cells and macrophages in the germinal center of lymphoid follicles. From the GALT the prion agent spreads to other secondary lymphoid tissues including lymph nodes and the spleen over the next several months (van Keulen et al., 2000). The mechanism of prion agent dissemination in secondary lymphoid tissues has not been determined but is thought to be via prion-infected migratory cells that travel in the lymph. A blood borne route is also possible since low levels of prion

infectivity have been found in the blood of sheep with scrapie and humans with vCJD (reviewed by Ironside, 2006).

In scrapie-infected sheep, spread of the prion agent from the gut to the CNS occurs via peripheral nerve fibers. From the GALT, the prion agent enters the sympathetic nerves that innervate secondary lymphoid tissues and spreads to the spinal cord via the autonomic nervous system (McBride et al., 2001). The prion agent then ascends the spinal cord along spinal tracts into the brain (Figure 29.3) (van Keulen et al., 2000). In a second pathway, after prion infection of the GALT, there is a delay before agent replication is found in the enteric nervous system. From these sites, the prion agent enters the vagal nerve and spreads to the brainstem where initial agent deposition is found in the dorsal motor nucleus of the vagus (Beekes et al., 1998; van Keulen et al., 2000). Early PrP^{Sc} deposition in this nucleus is indicative of neuroinvasion following oral ingestion. In vCJD, spread from secondary lymphoid tissues to the CNS is likely to take months to years.

Evidence for oral ingestion in vCJD is provided by the peripheral PrP^{Sc} distribution. In humans with vCJD, PrP^{Sc} is present in the ileum and the sympathetic ganglia that provide autonomic innervation to the gut (reviewed by Hilton, 2006). Variant CJD infection is also present in FDCs in secondary lymphoid tissues including the Peyer's patches, tonsil, spleen, lymph nodes, and appendix. This distribution of the prion agent suggests that agent entry via oral ingestion results in the spread of vCJD infection to distal secondary lymphoid tissues (reviewed by Hilton, 2006). This peripheral distribution of the prion agent in lymphoid tissue and autonomic nervous system of the gut is not found in sCJD or the familial human prion diseases suggesting that vCJD is acquired by peripheral exposure.

FIGURE 29.3. The stages of prion agent infection and neuroinvasion following oral ingestion of scrapie in sheep.

29.6. CNS Pathogenesis of Sporadic, Familial, and Iatrogenic Prion Diseases

29.6.1. Sporadic CJD

In sCJD the process or events that lead to PrP^{Sc} formation and accumulation are thought to be limited to the CNS. The apparent absence of prion infection in secondary lymphoid tissues in patients with sCJD is cited as evidence against acquisition of prion infection from peripheral exposure. PrP^{Sc} has not been found in the spleen, lymph nodes, tonsil or appendix in patients with sCJD (Head et al., 2004). There is also an absence of infection in the sympathetic ganglia that provide autonomic innervation to the gut, indicating that it is unlikely that there is infection of the enteric nervous system and GALT. However, prion infection has been detected in the peripheral nervous system of patients with sCJD. PrP^{Sc} deposition has been found in retina, trigeminal ganglion, the olfactory nerves and epithelium, dorsal root ganglia and an occasional peripheral nerve (Head et al., 2004). This distribution is consistent with spread of the prion agent away from the CNS along cranial or spinal nerve fibers. PrP^{Sc} has also been found in skeletal muscle of patients with sCJD (Glatzel et al., 2003).

29.6.2. Familial Prion Disease

In familial prion diseases germ line mutations in the prion protein gene leads to PrP^{Sc} deposition in the brain and nervous system. Prion agent has not been found in peripheral tissues in the limited number of familial prion disease cases that have been examined.

29.6.3. Iatrogenic CJD

Iatrogenic CJD can be acquired by either peripheral or CNS exposure to the prion agent from donor tissues or contaminated surgical equipment. The length of time to development of prion disease appears to be related to the site of prion inoculation. Shorter incubation periods are typically found following direct prion exposure to the brain (e.g., contact with stereotactic electrodes or instruments during neurosurgery) while longer incubation periods are seen following peripheral exposure (e.g., intramuscular injection of growth hormone) to the prion agent. In the latter cases, the incubation period can be up to several decades in duration (reviewed by Will, 2003). Due to the low number of iCJD cases, there are few studies examining the peripheral distribution of prion agent. One study reported the presence of PrP^{Sc} in the dorsal root ganglia and a few peripheral nerve fibers of two patients with dura mater related iCJD (Ishida et al., 2005). The pathway of neuroinvasion in iCJD associated with growth hormone therapy is less clear and prion infection was not found in secondary lymphoid tissues of a single patient, but the trigeminal ganglion and dorsal root ganglion were found to be sites

of prion infection (Head et al., 2004). This limited amount of data would suggest that the prion agent is restricted to the CNS or PNS in iCJD.

29.7. Prion Agent Interaction with the Immune System

The immune system plays a central role in the pathogenesis of prion infection. In the acquired human prion diseases, it is the initial site of agent replication prior to entry into the nervous system but the immune system does not appear to be essential in the pathogenesis of the familial and sporadic human prion diseases. Following peripheral exposure to the prion agent, the immune system can amplify prion infection but, interestingly, the adaptive immune response does not play a role in the clearance of the prion agent.

29.7.1. Prion Infection of Secondary Lymphoid Tissues

In the 1960s it was first described that the spleen is an early site of prion agent replication following peripheral scrapie infection of mice (Eklund and Hadlow, 1969). Prion replication in the spleen is present shortly after peripheral exposure and reaches a plateau level prior to detection of prion agent in the brain. Mice that receive immunosuppressive therapy or splenectomy prior to peripheral inoculation experience a delay in prion replication in the periphery and spread to the CNS (Kimberlin and Walker, 1989). Mice that are deficient in B cells also are resistant to peripheral prion infection, but B cells do not appear to be a target for prion infection (reviewed by Aguzzi and Heikenwalder, 2005 and by Mabbott and Turner, 2005). One site of PrP^{Sc} deposition in the spleen and lymph nodes is in follicular dendritic cells (FDCs), and PrP^C expression on FDCs is required for prion infection of these cells (reviewed by Aguzzi and Heikenwalder, 2005 and by Mabbott and Turner, 2005). FDCs are located in the germinal center of secondary lymphoid tissues and play a role in the presentation of antigen to B cells. B cells are important in FDC maturation and they secrete lymphotoxins (LT) that bind to LT receptors on FDCs. In the absence of B cells or LT, FDCs do not mature and are not susceptible to prion infection.

Several lines of evidence indicate that FDCs are important in prion agent replication in secondary lymphoid tissue (reviewed by Aguzzi and Heikenwalder, 2005 and by Mabbott and Turner, 2005). Temporary de-differentiation of FDCs by injection of antibodies to LT receptors causes a loss of mature FDCs, a disorganization of the cytoarchitecture of the germinal center, and a delay or complete block in peripheral scrapie replication and neuroinvasion. A permanent loss of mature FDCs and disorganization of lymphoid structure is also found in null mice that lack LT or LT receptor genes. When these mice are peripherally challenged with the prion agent, they

also demonstrate a greatly reduced capacity for agent replication and, in some cases, a complete block in peripheral prion pathogenesis. These studies indicate that FDCs are important sites of prion agent replication in lymphoid tissues and provide a critical step in the early pathogenesis of prion diseases.

29.7.2. Trafficking of the Prion Agent to Secondary Lymphoid Tissues

The complement system plays a role in the transport of the prion agent from peripheral sites of entry to FDCs in secondary lymphoid tissue (reviewed by Mabbott, 2004). Mice that lack the C3 complement receptor have a delay in prion replication in the spleen and in the onset of neurological disease. Complement component C3 plays a pivotal role in activation of both the classical and alternative complement pathways. Mice that lack the C1qa component or factor B and C2 complement components are deficient in the classical and alternative complement pathways, respectively, and these mice have a delay in prion agent replication in the spleen. As a result, they survive longer than wild type mice following intraperitoneal prion infection. If low doses of the prion agent are inoculated into the periphery of these complement-deficient mice, they do not develop prion disease while wild type mice remain susceptible to prion disease following peripheral infection. Since mice that lack the C1qa component are the most resistant to peripheral prion challenge, this complement factor may directly bind to PrP^{Sc} and activate the classical complement pathway. FDCs have complement receptors on their cell surface and targeting of the prion agent to FDCs may involve binding of PrP^{Sc}-complement complexes to these receptors.

29.7.3. Trafficking of the Prion Agent to the Central Nervous System

The transfer of the prion agent from FDCs to peripheral nerves in the secondary lymphoid tissues is necessary for neuroinvasion. The FDCs are physically separated from the sympathetic nerve fibers but in chemokine receptor CXCR5 null mice there is a reorganization of the germinal center and the sympathetic nerves are now in close proximity to FDCs. Peripheral prion infection in these mice resulted in faster neuroinvasion into the spinal cord indicating that there is accelerated transfer of prion agent from the FDCs to the peripheral nervous system (Prinz et al., 2003). In transgenic mice that overexpress nerve growth factor, there is hyperinnervation of the sympathetic nervous system; these mice have a faster onset of prion agent replication in the spinal cord after peripheral challenge even though the onset of replication in the spleen is similar to wild type mice (Glatzel et al., 2001). Inhibition of sympathetic innervation in newborn mice with antibodies to nerve growth factor or chemical sympathectomy causes a delay in prion agent replication in the CNS (Glatzel et al., 2001). The transfer of the prion agent from FDCs to sympathetic nerves is crucial for prion neuroinvasion into the CNS.

29.7.4. Role of Inflammation in the Peripheral Distribution and Transmission of the Prion Agent

In a healthy host peripheral prion infection primarily involves infection of secondary lymphoid tissues such as the lymph nodes and spleen. In mice with chronic inflammation in a peripheral organ that normally does not contain secondary lymphoid tissue, prion agent replication can also be found. In rodent models of nephritis, pancreatitis and hepatitis in which there is upregulation of lymphotoxins in the kidney, pancreas or liver, respectively, lymphoid tissue containing FDCs can develop in the inflamed organ. Following peripheral inoculation, prion infection can be established in these organs since transient secondary lymphoid tissues are present (Heikenwalder et al., 2005). In one model of prion infection in the kidney of mice with glomerulonephritis, prions could also be found in urine (Seeger et al., 2005). These findings indicate that chronic inflammation can lead to an altered organ tropism of the prion agent and induce excretion of the prion agent from a secretory organ.

In sheep with mastitis, a chronic inflammation of the mammary gland, and concurrent scrapie, prion infection is present in FDCs and macrophages in lymphoid follicles that develop adjacent to mammary ducts (Ligios et al., 2005). Although, there are no accounts of prion shedding from colostrum in scrapie-infected sheep without mastitis, macrophages can be shed into the milk of sheep with mastitis. Secretion of the scrapie-infected macrophages in colostrum of sheep with mastitis could potentially play a role in vertical transmission of scrapie since the route of spread from ewe to lamb has not been determined.

Summary

The human prion diseases are a diverse group of neurodegenerative diseases that are classified by several criteria including disease etiology, *PRNP* polymorphisms at codon 129, PrP^{Sc} types and subtypes, prion incubation period, clinical presentation, neuropathology and disease duration. CJD is unique in that it can have a sporadic, inherited, and acquired etiology, and all three forms can subsequently be transmitted following experimental inoculation of brain tissue. PrP^{Sc} is an unusual pathogen that fails to induce a prion-specific host immune response, but PrP^{Sc}-induced damage to the brain likely causes a proinflammatory response that contributes to neurodegeneration. The human prion diseases are primarily localized to the nervous system, but vCJD also has a peripheral distribution in secondary lymphoid tissues that is consistent with oral exposure to BSE. The prion agent uses the immune system for targeting to lymphoid organs, agent replication, and neuroinvasion via fibers that innervate lymphoid tissues. In chronic inflammatory conditions in which lymphoid organogenesis can occur in non-lymphoid tissues, ectopic prion infection can be established and could play a role in prion transmission.

Review Questions/Problems

1. What is a prion disease?
2. What is the “Protein-only hypothesis”?
3. What are the major types of human prion diseases based on clinical phenotypes?
4. What are the major PrP^{Sc} types in human prion diseases?
5. After peripheral infection, prion neuroinvasion is mediated through what cell type?
6. What is the role of B cells in prion neuroinvasion?

Glaucoma

Deven Tuli and Carl B. Camras

Keywords Glaucoma, Intraocular pressure, Optic nerve, Retinal ganglion cell

30.1. Introduction

The word glaucoma came from ancient Greek (Hippocrates, approximately 400 BC), meaning clouded or blue-green hue, most likely describing a patient having a cloudy cornea or advanced cataract precipitated by chronic elevated pressure. Over the last 100 years, further understanding of the concept of glaucoma has accelerated.

Currently, glaucoma is defined as a disturbance of the structural or functional integrity of the optic nerve that causes characteristic changes in the optic nerve, which may also lead to specific visual field defects over time. This disturbance usually can be diminished by adequate lowering of intraocular pressure (IOP). Some subsets of patients can exhibit the characteristic optic nerve damage and visual field defects while having an IOP within the normal range (normal tension glaucoma).

Primary open-angle glaucoma (POAG) is a multifactorial chronic optic neuropathy with a characteristic acquired loss of optic nerve fibers. Cupping and atrophy of the optic disc occur in the absence of other known causes. Such damage develops in the presence of open anterior chamber angles. It produces characteristic visual field abnormalities. IOP is too high for the continued health of the eye.

Individuals who maintain elevated IOP in the absence of nerve damage or visual field loss are considered at risk for developing glaucoma and have been termed ocular hypertensives. POAG is a major worldwide health concern because of its usually asymptomatic but progressive nature, and because it is the leading cause of irreversible blindness in the world. With appropriate screening and treatment, glaucoma usually can be identified and treated to prevent significant visual loss.

30.2. Epidemiology

30.2.1. Prevalence

In the United States (US), multiple population studies [e.g., Framingham (Leibowitz et al., 1980), Baltimore (Tielsch et al., 1991), Barbados (Leske et al., 1997)] have been performed to estimate the prevalence of eye disease, including POAG and ocular hypertension (OHT).

Estimates of the prevalence of glaucoma (Friedman et al., 2004; Table 30.1) and blindness (Congdon et al., 2004; Figure 30.1) in the US demonstrate the following: glaucoma is a leading cause of irreversible blindness, second only to macular degeneration; only one half of the people who have glaucoma may be aware that they have the disease; and more than 2.25 million Americans aged 40 years and older have POAG.

More than 1.6 million have significant visual impairment from glaucoma, with 150,000 bilaterally blind in the US alone (Tielsch et al., 1991). These statistics emphasize the need to identify and closely monitor those at risk for glaucomatous damage.

Approximately 6.7 million people are bilaterally blind from POAG worldwide, and more than 2 million people will develop POAG each year (Quigley, 1996).

30.2.2. Prognosis

Several studies (Gordon et al., 2002) have shown that the incidence of new onset of glaucomatous damage in previously unaffected patients to be approximately 2.6 to 3% in patients with IOPs 21 to 25 mm Hg, 12 to 26% with IOPs 26 to 30 mm Hg, and approximately 42% with IOP higher than 30 mm Hg. The Ocular Hypertension Treatment Study (OHTS) found that approximately 10% of patients with IOPs ranging from 24 to 31 mm Hg but with no clinical signs of glaucoma at baseline develop glaucoma over 5 years, with conversion to glaucoma reduced by 50% if patients are preemptively started on IOP-

lowering therapy (Kass et al., 2002). Significant subsets of higher and lower risk exist when pachymetry (central corneal thickness [CCT]) is taken into account.

Some patients' first sign of morbidity from elevated IOP can be presentation with sudden loss of vision due to a central retinal vein occlusion (CRVO). Elevated IOP is the second most common risk factor for CRVO behind systemic hypertension.

30.2.3. Risk Factors

30.2.3.1. Intraocular Pressure

In eyes suspected of being affected with glaucoma, loss of visual field develops at a rate of approximately 1 to 3 percent per year of observation (Gordon et al., 2002). High IOP is the most important risk factor (Table 30.2). The relative importance of other risk factors also is indicated in Table 30.2. In population-based surveys, between 25 and 50 % of those with glaucomatous damage to the optic nerve have IOP in the normal range. However, the probability of injury increases exponentially with higher IOP (Heijl et al., 2002). Large diurnal fluctuation in IOP is another independent risk factor for glaucoma (Nouri-Mahdavi et al., 2004).

FIGURE 30.1. Causes of blindness (best-corrected visual acuity <6/60 [$<20/200$] in the better-seeing eye) by race/ethnicity. AMD indicates age-related macular degeneration; DR, diabetic retinopathy. TABLE 30.2. Risk factors for glaucoma.

Established	Highly probable	Possible
Elevated IOP	Race (blacks*)	Presence (or absence) of diabetes
Thin CCT	Positive family history	Hypertension
Increasing age	Low diastolic perfusion pressure	
Large cup to disc ratio	Migraines	
	IOP fluctuations	
	Sleep apnea	
	Immunological disorders	
	Myopia	

IOP = Intraocular Pressure; CCT = Central Corneal Thickness; *In US, West Africa, Caribbean.

30.2.3.2. Race

Prevalence of POAG is 3–4 times higher in blacks than in whites in the US (Tielsch et al., 1991; Friedman et al., 2004). Glaucoma is the most common cause of irreversible blindness in the US among people of African or Hispanic descent (Congdon et al., 2004; Figure 30.1). Blacks in the US are more likely to develop glaucoma early in life, and they tend to have a more aggressive form of the disease.

The Barbados Eye Study (Leske et al., 1997) over 4 years showed a 5 times higher incidence of developing glaucoma in a group of black ocular hypertensives as compared with a predominantly white population. Some population studies have found the mean IOP in blacks to be higher than Caucasian controls. Other studies (e.g., Tielsch et al., 1991) found no difference. Consequently, further studies are required to clarify this issue.

The OHTS (Brandt et al., 2001) demonstrated that black patients in the US overall may have reduced CCT, thereby leading to underestimation of true IOP. The reduced CCT was associated with a higher risk of developing glaucoma. Therefore, pachymetry measurement is particularly important in African-American patients who are glaucoma suspects. In blacks, the OHTS also demonstrated a larger cup to disc ratio, which was an independent risk factor for the development of glaucoma (Feuer et al., 2002; Gordon et al., 2002; Table 30.2). These two confounding variables discovered on the multivariate analysis appeared to account for the apparent increased risk in blacks demonstrated in the univariate analysis (Gordon et al., 2002).

30.2.3.3. Age

Age older than 40 years is a risk factor for the development of POAG. Up to 15% of African-American men are affected by the ninth decade of life (Friedman et al., 2004; Table 30.1). Consequently, glaucoma is found to be more prevalent in the aging population, even after compensating for the mean rise in IOP with increasing age in the US. However, the disease itself is not limited to only middle-aged and elderly individuals.

30.2.3.4. Central Corneal Thickness

CCT is an important risk factor for the development of glaucoma (Gordon et al., 2002; Figure 30.2). CCT likely influences the measurement of IOP with many tonometers, including applanation techniques (Brandt et al., 2001). Increased CCT beyond the mean of 545 μm causes overestimation of IOP; lower CCT translates into underestimation of the IOP. A thin cornea (for example, 480 μm) may occur with glaucomatous visual field loss despite normal applanation IOP because the measurements are fallaciously low. Conversely, a thick cornea (for example, 620 μm) might occur in an eye with high IOP, normal visual fields and a normal optic nerve because it results in false overestimation of true IOP. Ehlers et al. (1975) extrapolated that applanation tonometry is overestimated or underestimated by approximately 5 mm Hg for every 70 μm difference in measured CCT from mean thickness. It is also possible that central corneal thickness may itself constitute an intrinsic risk (or protective) factor for glaucomatous optic nerve damage independent of its ability to affect the IOP measurement.

30.2.3.5. Family History

Relatives of those with glaucoma are more likely to have the disease (Drance et al., 1981). However, there is no clear mendelian pattern of inheritance for glaucoma. The Rotterdam Eye Study (Wolfs et al., 2000) concluded that the prevalence of glaucoma was 10.4% in siblings of patients with glaucoma and the relative risk of having POAG increased 9.2-fold for individuals with a relative with POAG. High IOP may be the inherited feature of glaucoma, or inherited risk factors independent of IOP may be involved.

30.2.3.6. Other Factors

Some reports have suggested an association between high blood pressure and glaucoma, but this relation is not fully understood and is not uniformly observed. There appears to be a subset of patients with low diastolic perfusion pressures who are at higher risk for POAG (Wilson et al., 1987). Some studies indicate that patients with diabetes have higher IOPs and a higher rate of glaucoma than people without diabetes. However, other studies fail to demonstrate this relationship. In a study in which the presence of diabetes mellitus was self-reported, diabetes protected against the development of glaucoma (Gordon et al., 2002). Other abnormalities in vascular function, including migraine headache (Cursiefen et al., 2000) and vasospasm in the extremities (Broadway and Drance, 1998), appear to be associated with glaucoma as demonstrated in some studies.

Sleep apnea has been shown to be a risk factor for glaucoma in some studies (Pearson, 2000). Myopia may be another risk factor for glaucoma (Daubs and Crick, 1981). The relatively thin eye wall and large globe in severely nearsighted people suggest a possible susceptibility to stretching under the influence of IOP. The association between factors such as concurrent cardiovascular disease (Tielsch, 1991) has not been demonstrated consistently.

FIGURE 30.2. Risk for developing primary open glaucoma varies with central corneal thickness. The numbers and percentage of participants in the observation group who developed primary open-angle glaucoma (median follow-up, 72 months) are indicated below each bar. Participants are grouped by baseline intraocular pressure of ≤ 23.75 mm Hg, > 23.75 mm Hg to ≤ 25.75 mm Hg, and > 25.75 mm Hg and by central corneal thickness measurements of ≤ 555 μm , > 555 μm to ≤ 588 μm , and > 588 μm . These percentages are not adjusted for length of follow-up. Reproduced with permission from: Gordon MO, Beiser JA, Brandt JD, Heuer DK, Higginbotham EJ, Johnson CA, Keltner JL, Miller JP, Parrish RK 2nd, Wilson MR, Kass MA (2002) The Ocular Hypertension Treatment Study: baseline factors that predict the onset of primary open-angle glaucoma. *Arch Ophthalmol* 120: 714–20.

FIGURE 30.3. Several mechanisms have been hypothesized to have a role in causing retinal ganglion cell death in glaucoma. IOP indicate intraocular pressure. Reproduced with permission from: Weinreb and Levin (1999).

30.3. Pathophysiology

In general, the cause of glaucomatous optic neuropathy is unknown. The disease affects the individual axons of the optic nerve, which may die by apoptosis, also known as

programmed cell death. Multiple theories exist concerning how IOP can be one of the factors that initiates glaucomatous damage in a patient (Figure 30.3). Two of the fundamental theories include the mechanical and vascular theory.

30.3.1. Mechanical Theory

The mechanical compression theory (Quigley et al., 1981) suggests that elevated IOP causes a backward bowing of the lamina cribrosa, resulting in kinking of the axons as they exit through the lamina pores. This may deprive the axons of neurotrophins or interfere with axoplasmic flow, thereby triggering cell death. Neurotrophins increase RGC survival and may be produced by the RGCs themselves (Perez and Caminos, 1995). Damaged RGC axons are affected by neurotrophin deprivation. With the loss of neurotrophic support of the RGCs, slow death is inevitable. Brain derived neurotrophic factor (BDNF) is one such neurotrophin that can temporarily increase the survival of the RGCs by inhibiting the excitotoxicity-related cell death. Deficiency of these protective factors may contribute to glaucomatous optic neuropathy.

30.3.2. Vascular Theory

The vascular theory (Hayreh et al., 1970) proposes that cell death is triggered by ischemia, whether induced by elevated IOP or as a primary insult. Studies done to evaluate the circulation of the optic nerve using the laser Doppler flowmetry have shown diminished blood flow in the optic nerves of eyes with POAG (Grunwald et al., 1998).

30.3.3. Contributory Mechanisms

Complementary to vascular compromise and mechanically impaired axoplasmic flow, additional pathogenic mechanisms (Figures 30.3 & 30.4) that underlie glaucomatous optic neuropathy include excitotoxic damage from excessive retinal glutamate, peroxynitrite toxicity from increased nitric oxide synthase activity, immune-mediated nerve damage, and oxidative stress (Naskar and Dreyer, 2001).

Beyond the neuronal degeneration that results from the primary insult or risk factors in glaucoma, there is an expanding cascade of events called “*secondary degeneration*”, during which RGCs are gradually damaged from the unfavorable “*milieu*” of the neighboring degenerating neurons (Schwartz, 2005).

Many pathophysiological mediators common to all neurodegenerative diseases, including glaucoma, have been identified, such as increase in glutamate, conformationally altered self proteins, increase in inflammation-associated factors (cyclooxygenase-2 [COX-2], tumor necrosis factor [TNF- α], nitric oxide [NO]), increase in extracellular matrix proteins and growth-associated inhibitors (myelin-related proteins), oxidative stress, and malfunctioning of local immune cells (microglia). These mediators evoke a response for which the tolerance of the neural tissue is minimal.

The important mechanisms of neuronal compromise or death are discussed briefly.

30.3.3.1. Immune Mechanisms

Optic nerve crush injury models have been studied in mice and rats by Schwartz and others (Schwartz, 2004). Experiments

conducted with these models have shown that nerve-derived extracellular risk factors induce intracellular death signals, resulting in neuronal death. Neural injury has long been considered self destructive and progressive primarily due to the autoimmunity to self antigen. The anti-self antigen response has been shown in these experiments to have a coincidental beneficial and modulating effect (Schwartz, 2005). The autoimmune T cells limit the activity of the microglial framework and blood-borne macrophages, affecting their ability to deal with a local excitatory situation. Such a controlling effect has a beneficial impact on both survival and regrowth. In the absence of such control, this phenomenon can become destructive, inducing an autoimmune disease. Boosting the beneficial effect by the use of a safe antigen that can cross-react with self-antigens at the site under stress might provide an effective therapeutic approach that influences both rescue and regeneration (Schwartz, 2005). Proper control of autoimmunity that titrates the local microglia response and the infiltrating macrophages may be a therapy that boosts protection and regeneration. Intervention may be applied at the level of the nerve-derived risk factor, at the interface between the secondary mediator and the intracellular signal, or at the level of the intercellular signal itself. Copolymer 1 (Cop-1), an approved drug for the treatment of multiple sclerosis, can be used as a treatment for autoimmune diseases and as a therapeutic vaccine for neurodegenerative diseases (Kipnis and Schwartz, 2002). It has been proposed that the protective effect of Cop-1 vaccination is obtained through a well-controlled inflammatory reaction, and that the activity of Cop-1 in driving this reaction derives from its ability to serve as a “universal antigen” by weakly activating a wide spectrum of self-reactive T cells (Kipnis and Schwartz, 2002). These results have special implications for glaucoma therapy since glaucoma is the most common cause of optic neuropathy.

30.3.3.2. Apoptosis

Apoptosis is classically defined by an orderly pattern of internucleosomal DNA fragmentation, chromosome clumping, cell shrinkage, and membrane blebbing (Wyllie et al., 1980). This is followed by disassembly of the cell into multiple membrane-enclosed vesicles that are engulfed by neighboring cells without inciting inflammation. Apoptosis has often been labeled as “*programmed or physiological cell death*.” Necrosis, on the contrary, is characterized by cellular swelling, disruption of organelle and plasma membranes, random DNA fragmentation, and uncontrolled release of cellular contents into the extracellular space, often resulting in inflammation.

Several gene families have been identified that play either positive or negative roles in determining whether a cell (in glaucoma, the RGC) will undergo apoptosis. Caspases are cysteine proteases that play a central role in both propagating apoptotic signals and carrying out disassembly of the cell (Hutchins and Barger, 1998). The prototypical mammalian caspase is interleukin-1 converting enzyme. Caspases are always present in the cytoplasm, ready to be activated as the mediators of apoptosis (Thornberry and Lazebnik, 1998).

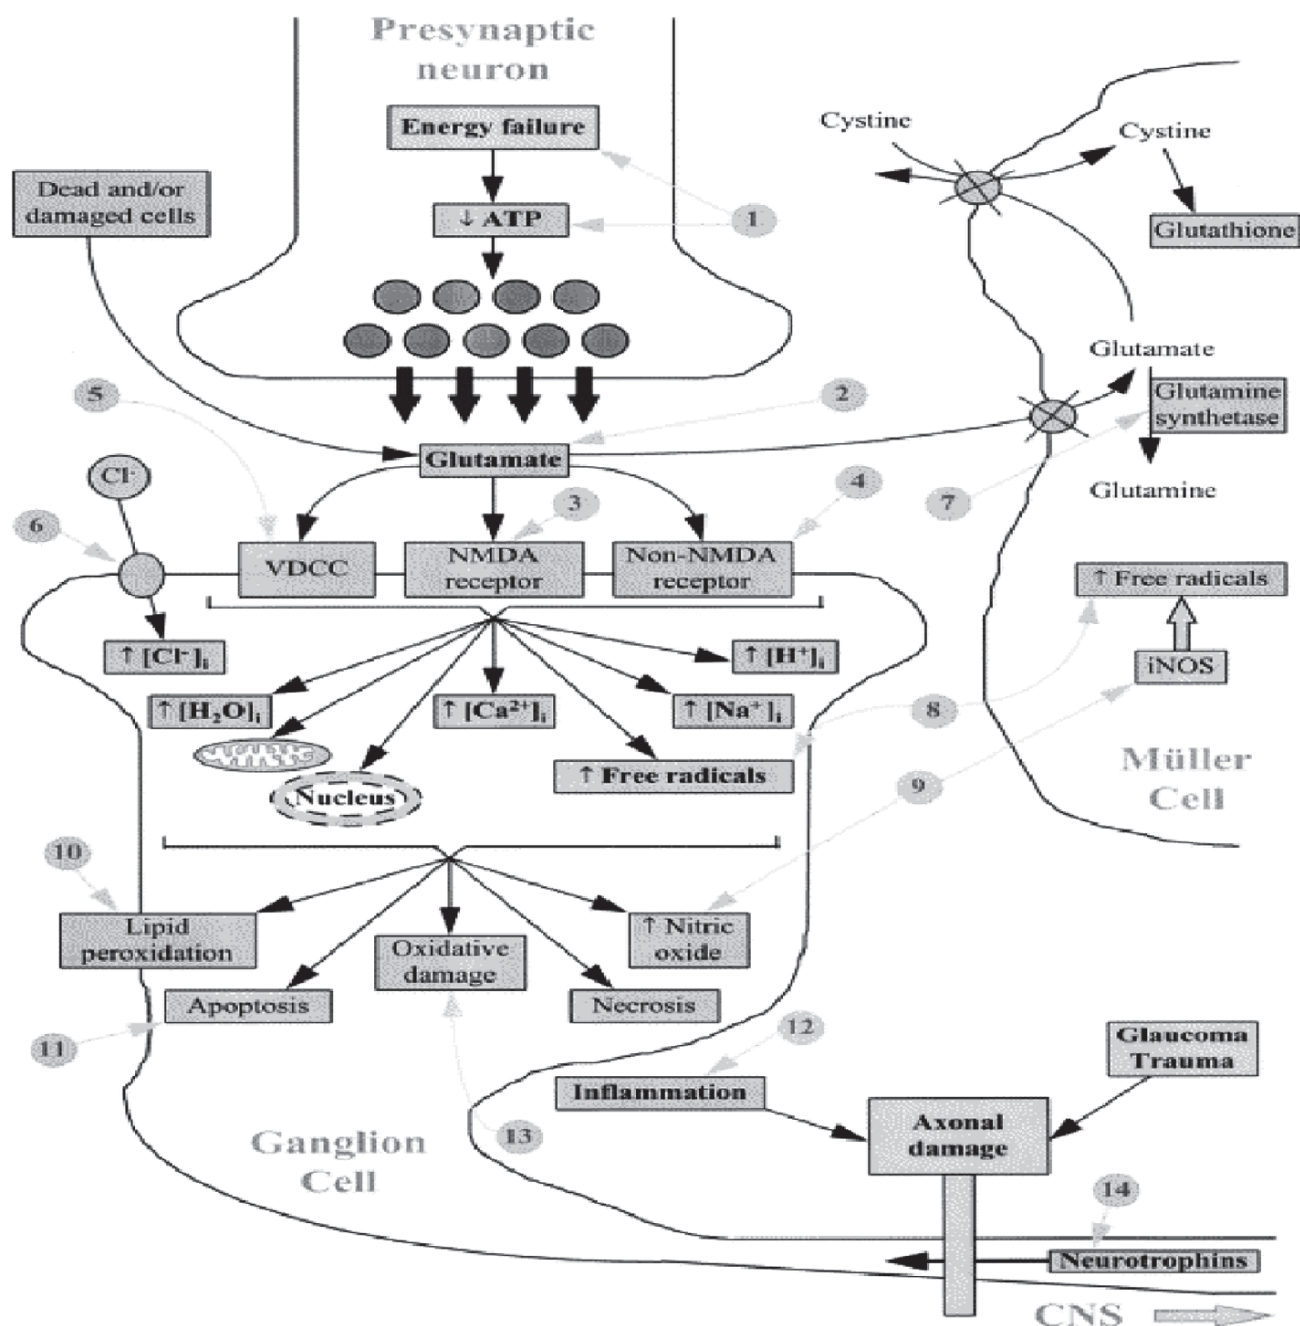

FIGURE 30.4. Diagrammatic summary of potential targets for intervention in ganglion cell death. 1) Prevent energy loss, 2) reduce extracellular glutamate, 3) block ionotropic NMDA receptors, 4) block non-NMDA ionotropic glutamate receptors, 5) block excessive influx of Ca^{2+} through voltage-gated channels, 6) prevent influx of chloride and water, 7) enhance intracellular glutamate catabolism, 8) prevent excessive production of free radicals, 9) prevent detrimental effects of nitric oxide, 10) prevent lipid peroxidation, 11) prevent induction of apoptosis, 12) reduce any inflammation, 13) stop oxidative damage, and 14) maintain neurotrophin support. Reproduced with permission from: Osborne NN, Ugarte M, Chao M, Chidlow G, Bae JH, Wood JP, Nash MS (1999) Neuroprotection in relation to retinal ischemia and relevance to glaucoma. *Surv Ophthalmol* 43 Suppl 1:S102–S128.

They cleave a wide variety of critical functional and structural cellular proteins, and they also convert other caspases from proenzymes to active forms. Many triggers activate caspases, including increased intracellular calcium, changes in cellular energy balance, and adenosine 3'5' cyclic phosphate.

The main inhibitors of apoptosis are Bcl-2 and related proteins. They have multiple complex functions, such as inhibiting intermediate proteins that activate caspases, gauging intracellular damage and maintaining organelle integrity in ways that are not fully understood. For example, over expres-

sion of Bcl-2 inhibits both apoptotic and necrotic cell death by suppressing lipid peroxidation (Adams and Cory, 1998).

30.3.3.3. *Glutamate-Induced Excitotoxicity*

The excitatory amino acid glutamate is known to cause neurotoxicity via binding of glutamate to the *N*-methyl-D-aspartate (NMDA) receptor and the kainate receptors. This can be secondary to many types of cellular damage, including other final common pathways of damage such as oxidative stress or free radical damage (Osborne et al., 1999). Activation of these receptors allows entry of excessive amounts of calcium. Calcium is normally used by cells as a critical intracellular signaling molecule and is involved in many diverse functions, including control of cell-surface ion channels, regulation of enzymes, and even self-regulation of its intracellular level. Abnormally high concentrations of calcium lead to inappropriate activation of complex cascades of proteases, nucleases, and lipases. These directly damage cellular constituents and lead to ganglion cell death.

One neuroprotective strategy, therefore, is to interrupt the resultant excitotoxic cascade by blocking the NMDA receptor. Amongst the several pharmacological drugs tried, MK 801 is one drug that demonstrated neuroprotective properties in pressure-induced and reperfusion-injury animal models of RGC toxicity (Lam et al., 1997). Memantine is a clinically well-tolerated NMDA receptor antagonist (Lipton, 2003). The results of its effectiveness in Alzheimer are encouraging (Reisberg et al., 2003).

30.3.3.4. *Free Radicals*

Free radicals are generated not only through activation of glutamate receptors but also as the inevitable by-product of normal oxidative metabolism. This is especially true in the retina and the RGCs, which have an extremely high metabolic rate. This triggers further changes including calcium release that causes cell damage (as summarized in Sect. 30.3.3.3. above). Endogenous antioxidants such as vitamins E and C, superoxide dismutase (Greenlund et al., 1995), and glutathione normally inactivate free radicals.

30.3.3.5. *Nitric Oxide Synthase*

Nitric Oxide Synthase (NOS) is postulated to have a role in RGC axonal toxicity. Inducible NOS is known to be up regulated in the optic nerve in glaucoma (Liu and Neufeld, 2001). Inhibitors of NOS, such as 3-aminoguanidine, decreased the RGC loss by 70% in rat eyes with raised IOP (Neufeld et al., 1999).

30.3.3.6. *Dopamine Deficiency*

The origin of the pattern electroretinogram (PERG) response is predominantly the RGCs. Parkinson's disease related changes in retinal processing caused by changes in the dopaminergic amacrine, horizontal, and interplexiform cells may alter the receptive field composition of the RGC, thereby altering the PERG

response. Delayed PERG latencies in untreated patients with Parkinson's disease were restored with dopaminergic therapy (Jackson and Owsley, 2003). Further support that dopamine deficiency is responsible for changes in the RGC induced PERG is that PERG latencies are delayed in control adults given haloperidol, a dopamine antagonist (Bodis-Wollner and Tzelepi, 1998).

Dopamine has been recognized to have neuroprotective actions in glaucoma. Retinal dopaminergic cells can be detected by the immunohistochemical staining of tyrosine hydroxylase, the rate-limiting enzyme in dopamine synthesis. It has been observed that NMDA induced RGC toxicity dramatically decreased tyrosine hydroxylase immunostaining at the junction between the inner nuclear layer and inner plexiform layer in glaucoma (Kitaoka and Kumai, 2004).

30.3.3.7. *Heat-Shock Proteins*

Heat-shock proteins (Hsp) are known to be an intrinsic protection mechanism associated with an early response against physiologic and environmental stress (Wax and Tezel, 2002). Certain Hsp have special effects upon neurons, including Hsp 72, 27 and 60. Hsp 27 and 60 have been demonstrated to be upregulated in RGCs of glaucoma (Tezel et al., 2000). Recent work has shown that geranylgeranylacetone can induce Hsp 72 in RGCs and protect them from glaucomatous damage in a rat glaucoma model (Ishii et al., 2003).

30.3.3.8. *Activated Microglia*

Yuan and Neufeld (2001) investigated the potential participation of activated microglia, the resident defense cells of the central nervous system in causing optic nerve head (ONH) damage in glaucoma. In normal ONH, microglia do not contain transforming growth factor-beta (TGF-beta), COX-2, or TNF-alpha; however, in glaucomatous ONH, microglia contain abundant TGF-beta, TNF-alpha, and a few microglia are usually positive for COX-2. In glaucomatous ONH, microglia become actively phagocytic and produce cytokines, mediators, and enzymes that can alter the extracellular matrix. Findings from these authors suggest that activated microglia may participate in stabilizing the tissue early in the disease process, but, as the severity of the glaucomatous damage increases, the activated microglia may contribute to glaucomatous optic neuropathy (Yuan and Neufeld, 2001).

30.3.3.9. *Genetic Mutations*

Myocilin (MYOC) is one gene that has been associated with early- and late-onset POAG. The MYOC gene was mapped to the open-angle glaucoma locus (GLC1A) region of chromosome 1q25, and mutations were discovered in patients with adult and juvenile open-angle glaucoma. Mutations in this gene are found in 3 to 5% of adult-onset POAG patients and in 8 to 20% juvenile-onset POAG patients (Wiggs et al., 1998). Different mutations are associated with juvenile and adult glaucoma. In particular,

the most common mutation associated with adult glaucoma is a nonsense mutation, whereas all the mutations associated with juvenile glaucoma are missense mutations. Additionally, some of the mutations typically associated with adult glaucoma can cause more severe, earlier onset glaucoma when found in combination with DNA sequence variants in the CYP1B1 gene.

Using single large pedigrees affected by POAG, seven genetic loci have been described (GLC1A-G), and glaucoma-predisposing genes have been identified in three of these loci: GLC1A, myocilin (Wiggs et al., 1998); GLC1E, optineurin (Rezaie et al., 2002); and GLC1G, WDR36 (Monemi et al., 2005). Each of these genes is only responsible for a small fraction of cases of POAG, reflecting the small percentage of POAG that is inherited as a Mendelian trait rather than as a complex trait.

The optineurin protein may function to protect the optic nerve from TNF- α -mediated apoptosis, and the loss of function of this protein may decrease the threshold for RGC apoptosis in patients with glaucoma. Surprisingly, mutations in this gene do not appear to contribute significantly to the optic nerve degeneration that is a component of typical high-pressure POAG (Wiggs et al., 2003).

The exact role that IOP plays in combination with these other factors and the latter's significance in the initiation and progression of subsequent glaucomatous neuronal damage and cell death requires further studies.

30.4. Clinical Features

30.4.1. History

The initial patient interview is important in the evaluation for glaucoma. Because of the silent nature of POAG, patients usually will not present with any visual complaints until late in the course of the disease. A history should include the following:

1. Past ocular and medical history including:
 - Eye pain
 - Redness
 - Multicolored halos
 - Headache
 - Previous ocular disease such as cataracts, uveitis, diabetic retinopathy or vascular occlusions
 - Previous ocular laser or surgery
 - Ocular or head trauma
 - Pertinent vasculopathic systemic illnesses, including Raynauds phenomenon or migraine
2. Current medications, including any hypertensive medications (which may affect IOP) or corticosteroids used topically or systemically.
3. Family history of glaucoma.

30.4.2. Physical Exam

Screening the general population for POAG is most effective if targeted at those at high risk, such as African Americans

and elderly individuals, especially if the screening includes IOP measurements, assessment of the optic nerve and screening visual fields.

For individuals of age 65 years or above, recommended frequency for a comprehensive adult medical eye evaluation is 6 to 12 months when risk factors for glaucoma are present and 1 to 2 years in the absence of risk factors. For glaucoma suspect individuals under 40 years, the frequency of the eye evaluation should be 2 to 4 years and 5 to 10 years in the presence and absence of risk factors for glaucoma, respectively (American Academy of Ophthalmology: Preferred Practice Patterns, 2005a).

A standard comprehensive eye examination is performed on the initial visit. If any visual field or optic nerve changes consistent with glaucoma are present, additional appropriate testing should be done to establish a diagnosis.

In patients with glaucoma, factors that determine frequency of evaluations include the severity of damage, the stage of the disease, the rate of progression, the extent to which the IOP exceeds the target pressure, and the number and significance of other risk factors for damage to the optic nerve. If the target IOP has been achieved and there is no progression of damage, it is recommended (American Academy of Ophthalmology: Preferred Practice Patterns, 2005b) to follow up with ONH exam and visual field testing at 6 to 18-month intervals. On the contrary, if there is progression of damage and the target IOP has not been achieved, more frequent testing is required until stability is achieved.

30.4.2.1. Tonometry

IOP varies from hour-to-hour in any individual. Many studies indicate that the circadian rhythm of IOP peaks in the early hours of the morning. IOP often rises when a patient assumes a supine position. When checking IOP, record measurements for both eyes, the method used (Goldmann applanation is considered the standard), and the time of the measurement.

A difference between contralateral eyes of 3 mm Hg or more indicates greater suspicion of glaucoma. An average of a 10% difference between individual measurements is expected. In most circumstances, the measurements should be repeated on at least 2–3 occasions before deciding on a treatment plan. The measurement should be made at different times of the day to check for diurnal variation. A diurnal variation of more than 5–6 mm Hg indicates an increased risk for glaucoma.

30.4.2.2. Gonioscopy

The angle of the eye is examined by gonioscopy, which requires the use of special lenses. Gonioscopy is performed to rule out angle-closure or secondary causes of IOP elevation, such as angle recession, pigmentary glaucoma, and exfoliation syndrome. The peripheral contour of the iris is examined for plateau iris, and the trabecular meshwork for peripheral anterior synechiae, as well as for neovascular or inflammatory membranes.

Schlemm's canal may be seen if blood refluxes into the canal. This might indicate elevated episcleral venous pressure caused by conditions such as a carotid-cavernous fistula, Graves orbitopathy, or Sturge-Weber syndrome.

Ultrasound biomicroscopy is helpful in assessing the angle, iris, and ciliary body to rule out anatomical pathology and secondary causes of elevated IOP.

30.4.2.3. Optic Disc and Nerve Fiber Layer

The optic disc is examined to estimate the cup-to-disc ratio and to identify excavation typical of glaucoma. Stereoscopic viewing during slit-lamp examination improves the accuracy of disc evaluation, since the disc is a complex, three-dimensional structure (Figure 30.5). Single cutoff values for the cup to disc ratio designed to distinguish between normal subjects and those with glaucoma are imperfect for screening, since the normal ratio varies considerably with optic disc size. When the cup to disc ratio equals or exceeds 0.6, the probability of glaucoma increases dramatically. In screening for glaucoma, however, even combined criteria, including the level of IOP and the cup to disc ratio, identify only two thirds of patients.

The disc should be viewed stereoscopically to assess evidence for glaucomatous damage (Figure 30.5), including the following: cup to disc ratio in horizontal and vertical meridians; color and slope of the cup; appearance of the disc; progressive enlargement of the cup; evidence of nerve fiber layer damage using a red-free filter; notching or thinning of disc rim, particularly at the superior and inferior poles where nerve fibers often can be affected first; pallor; presence of hemorrhage (most common inferotemporally); asymmetry between discs; peripapillary atrophy (possible association with the development of glaucoma); or congenital nerve abnormalities. Stereo fundus photographs are required as a baseline for future comparisons (Figure 30.5).

Other imaging techniques that utilize different physical properties of light for optical analysis can document the status of the optic nerve and the nerve fiber layer. Furthermore, they can be used to detect changes over time (Medeiros et al., 2004). The value of these technologies for diagnosing glau-

coma and for determining progression over time is currently under active investigation.

Confocal scanning laser ophthalmoscopy can evaluate the optic disc and peripapillary retina in 3 dimensions and provide quantitative information about the cup, neuroretinal rim, and contour of the nerve fiber layer.

Scanning laser polarimetry measures the change in the polarization state of an incident laser light passing through the naturally birefringent nerve fiber layer to provide indirect estimates of peripapillary nerve fiber layer thickness.

Optical coherence tomography uses reflected light in a manner analogous to the use of sound waves in ultrasonography to create computerized cross-sectional images of the retina and optic disc, and also gives quantitative information about the peripapillary retinal nerve fiber layer thickness.

Fluorescein angiography, ocular blood flow analysis via laser Doppler flowmetry, color vision measurements, contrast sensitivity testing, and electrophysiological tests (e.g., pattern electroretinograms) are used as research tools in the evaluation of POAG patients. Routine clinical use is not advocated at this time.

30.4.2.4. Visual Field Testing

Automated threshold testing (e.g., Humphrey 24-2) is performed to evaluate for glaucomatous visual field defects. If the patient is unable to perform automated testing, Goldmann perimetry may be substituted. New onset glaucomatous defects are found most commonly as an early nasal step, temporal wedge, or paracentral scotoma (more frequent superiorly). Generalized depression also might occur, but is less specific for glaucomatous damage.

Swedish interactive thresholding algorithm (SITA)-based software decreases testing time and boosts reliability, especially in older patients (Schimiti et al., 2002). Short wavelength automated perimetry (SWAP) or blue-yellow perimetry may provide a more sensitive method of detecting visual field deficits, especially in patients with OHT without defects demonstrated by standard testing. If the Humphrey standard automated perimetry results are normal, SWAP should be considered to help detect visual field loss earlier.

FIGURE 30.5. Stereo photographs representing normal optic nerve head (left) and typical glaucomatous changes (right).

Recent studies suggest SWAP may detect visual loss or progression up to 3 to 5 years earlier than conventional perimetry, as well as in 12 to 42% of patients previously diagnosed with only OHT (Racette and Sample, 2003). Because the testing time may be lengthened, it may be tiring for some patients. However, new SITA-SWAP algorithm software may speed up the testing time and thus improve reliability (Bengtsson and Heijl, 2003).

The pupil size should be documented at each testing session since pupillary constriction can reduce retinal sensitivity and mimic progressive visual field loss.

To establish a reliable baseline, visual fields may have to be repeated several times on successive visits, especially if initial testing shows low reliability indices. Newer glaucoma progression analysis software can help identify reliable perimetric baselines, and probability-based analyses of subsequent fields can assist in distinguishing true progression over time from fluctuation or artifact. In follow-up, if a low risk for onset of glaucomatous damage is present, then repeat testing may be performed once a year. If a high risk of impending glaucomatous damage is present, then testing frequency is adjusted accordingly (as frequent as every few months).

Frequency doubling perimetry (also termed frequency doubling technology or FDT, which is enhanced with new MATRIX software) is a relatively new technology that may detect functional visual loss at an earlier stage in the glaucomatous disease process, thereby detecting more patients who currently are misdiagnosed as having OHT instead of early POAG. Current sensitivities and specificities are continuing to improve, but more baseline data are needed to determine under what circumstances these new techniques will prove to be most useful.

30.5. Differential Diagnosis

Several disorders may mimic glaucomatous ONH and/or visual field changes. Those that resemble structural glaucomatous optic neuropathy or interfere with assessment of glaucomatous cupping include optic disc anomalies, tilted discs, optic nerve drusen, optic nerve pits, optic nerve colobomas, myelinated nerve fibers, ischemic optic neuropathy and optic atrophy.

Factors that mimic glaucomatous visual field loss include: branch retinal artery occlusion; chorioretinal scars; retinal areas treated by photocoagulation or cryotherapy; demyelinating disorders; cerebrovascular accidents, tumors, or other lesions affecting the optic nerve, chiasm, optic tract, optic radiation, and/or the remaining course of nerve fibers to the occipital cortex. Other abnormalities that could account for "pseudo-glaucomatous" visual field defects or vision loss include vitreous hemorrhage, proliferative retinopathy or other retinal disorders.

As discussed in Sect. 30.2.3.4, variation in CCT from normal values may affect IOP measurements by yielding falsely high values when CCT is high.

30.6. Animal Models

Animal models for glaucoma have been used to study the pathophysiological basis of glaucoma. Animal based experiments are more representative than cell culture models particularly in the study of aqueous humor dynamics, the trabecular meshwork-ciliary muscle complex, retinal ganglion cells, ONH axons, ONH framework and vascular flow dynamics in glaucoma subtypes (Weinreb and Lindsey, 2005).

Conducting studies in animal models often are challenging and occasionally require anesthesia, which might affect the parameter being assessed. Conditioned reflex training may help elicit cooperation. Use of remote controlled implants and newer drug delivery options represent advances made on this front.

Animal experiments have provided excellent means to study medical and surgical treatments for glaucoma prior to human trials. Animal models are required to study *de novo* drugs and their structural and functional influence on ocular tissues.

Genetic modulation of animal models is another area of research. Mice are genetically engineered to suit experimental needs. New models are required and will be developed to advance our understanding of the glaucomatous disease process. Mouse mutants with glaucoma provide models for human glaucoma. From the clinical standpoint, some mouse models share occasional similarities with various aspects of glaucoma occurring in humans. The life span and replication time (one mouse year is equal to 30 human years) allow developmental and invasive studies and make it possible to follow glaucoma progression in a reasonable span of time (Chang et al., 2005). Some of the new mouse glaucoma models used are: *Gpnmb* with mutation on chromosome 6 to study iris pigment dispersion (Anderson et al., 2002); *Tryp1* with chromosome 4 mutation to study iris stromal atrophy (Anderson et al., 2002); *Nm2702* with chromosome 11 mutation to study inner retina loss and optic nerve cupping (Chang et al., 2005); *CALB/Rk* and *si/si* model to study early enlargement of optic cup or coloboma (Chang et al., 2005); *AKXD-28* for ganglion cell loss and optic nerve cupping (Anderson et al., 2001); and *nm 1839-* model for Axenfeld's syndrome, anterior segment dysgenesis or buphthalmos (Chang et al., 2005). The effect of glaucoma on the electroretinogram response has been evaluated in mice.

The pig as a model for glaucoma shares many phylogenetic similarities with that of the human and is more readily available compared to the monkey model (Ruiz-Ederra et al., 2005). The porcine retina is more similar to human than other large mammals such as dog, goat or cow. Techniques used for glaucoma diagnosis in humans such as optical coherence tomography or multi-focal electroretinography can be reliably studied in pig eyes. Studies of the pig aqueous outflow system demonstrate it to be an acceptable model for specific glaucomas (McMenamin and Steptoe, 1991).

The monkey model of OHT with its resultant optic neuropathy closely reflects the optic neurodegeneration associated with human glaucoma. Utilization of the glaucoma model in monkeys has helped to further the understanding of aqueous humor

TABLE 30.3. Advantages and limitations of several animal models of glaucoma.

dynamics, glaucomatous damage in the RGCs and other structures along the visual pathway, and the effects of pharmacological agents on ocular tissues (Rasmussen and Kaufman, 2005). Fundus photographs of glaucomatous monkeys show the morphologic changes consistent with human OHT with the advantage of observing progressive changes over a shorter period of time by withholding treatment despite very high IOPs (Gaasterland and Kupfer, 1974). The ability to correlate histologic changes in glaucomatous monkey eyes with functional and imaging data is a major advantage of the monkey model. Humphrey visual field defects can be performed by trained glaucomatous monkeys (Harwerth et al., 2002). The types of visual field defects are similar to those in glaucomatous humans.

Utilization of an experimental glaucoma model in non-human primates has led to advances in the understanding of glaucomatous changes in the visual pathways from photoreceptors to the visual cortex (Rasmussen and Kaufman, 2005). Newer investigative modalities such as contemporary perimetry techniques have been studied in primate models. Electroretinograms can be performed in monkeys to evaluate changes produced by glaucomatous optic neuropathy.

The choice of animal is governed by the objectives and requirements of the study (Table 30.3). Size of the animal eye, similarity with human eyes, cost and availability are factors that influence the selection of the animal type.

Summary

Glaucoma is defined as a disturbance of the structural or functional integrity of the optic nerve that causes characteristic changes in the optic nerve leading to defects in the visual field. If left untreated, it might eventually lead to blindness. Glaucoma is the leading cause of irreversible blindness throughout the world, and is second only to macular degeneration in the US. Amongst the risk factors, elevated IOP, thin CCT, increasing age and large cup to disc ratio are established. Concerning its pathogenesis,

mechanical and vascular theories are fundamental. In addition, many other mechanisms contribute such as immune factors, apoptosis, glutamate-induced excitotoxicity, free radicals, nitric acid synthase and genetic mutations. To assess glaucoma, tonometry, gonioscopy, examination of optic disc, and visual field testing are essential. Animal models for glaucoma have been used to study the pathophysiological basis of glaucoma, aqueous humor dynamics, the trabecular meshwork, the ciliary muscle, and retinal ganglion cells. Animal experiments have provided worthwhile means of evaluating of diagnostic modalities and treatments, both medical and surgical, for glaucoma.

Review Questions/Problems

- The estimated world population that is bilaterally blind from primary open angle glaucoma is:**
 - 2–3 million
 - 3–4 million
 - 4–5 million
 - 5–6 million
 - 6–7 million
- The most important risk factor for developing primary open angle glaucoma is:**
 - increasing age
 - thin central corneal thickness
 - African-American race
 - excessive intraocular pressure
 - large cup to disc ratio
- Mechanisms that might contribute to optic nerve damage in glaucoma include:**
 - apoptosis
 - glutamate-induced excitotoxicity
 - nitric oxide synthase
 - free radicals
 - all of the above
- Mutations in which of the following genes have been shown to be associated with the pathogenesis of glaucoma?**
 - GLC1A
 - myocilin
 - optineurin
 - GLC1G
 - all of the above
- Which of the following testing strategies is NOT considered standard practice in the evaluation of patients with primary open angle glaucoma?**

- a. tonometry
 - b. gonioscopy
 - c. visual field testing
 - d. optical coherence tomography
 - e. all of the above
- 6. All of the following are characteristic changes that might be observed in the optic nerve head in primary open angle glaucoma except:**
- a. increased cup to disc ratio
 - b. notching of the neural rim
 - c. disc hemorrhage
 - d. new vessels within the disc
 - e. all of the above
- 7. Ancillary techniques that might be used to evaluate patients with glaucoma include:**
- a. nerve fiber layer analyzer
 - b. confocal scanning laser ophthalmoscopy
 - c. ultrasound biomicroscopy
 - d. optical coherence tomography
 - e. all of the above
- 8. According to recent estimates, which of the following individuals is at highest risk of developing glaucoma?**
- a. African-American male, age 80 years
 - b. Hispanic female, age 60 years
 - c. Caucasian male, age 80 years
 - d. African-American female, age 70 years
 - e. Caucasian female, age 80 years
- 9. As per the mechanical theory of glaucoma pathogenesis, deprivation of which of the following factors may accelerate retinal ganglion cell loss?**
- a. heat-shock protein
 - b. calcium
 - c. neurotrophins
 - d. dopamine
 - e. glutamate
- 10. All of the following conditions may mimic glaucomatous visual field loss except:**
- a. branch retinal artery occlusion
 - b. retinitis pigmentosa
 - c. cerebrovascular accident
 - d. chorioretinal scar
 - e. none of the above
- 11. Briefly discuss the risk factors for primary open angle glaucoma.**
- 12. Enumerate the important mechanisms involved in pathogenesis of glaucomatous optic neuropathy.**
- 13. Discuss the immune mechanisms contributing to retinal ganglion cell damage in glaucoma.**

14. Outline the recent advances in the genetic basis for glaucomatous optic neuropathy.

15. Describe the role of animal models in our understanding of glaucoma.

16. Briefly discuss the prevalence of primary open angle glaucoma in the United States.

17. Outline the importance of central corneal thickness in glaucoma practice.

Stroke and Cerebrovascular Disease

Alison E. Baird

Keywords Atherosclerosis; Complement; Hemorrhagic stroke; Ischemic stroke; Stroke

31.1. Introduction

Strokes result from occlusion or rupture of blood vessels in the brain and are a leading cause of death and disability in the United States (US, Broderick et al., 1998). There are around 700,000 new and recurrent strokes per year in the US, with costs related to stroke estimated to be over \$60 billion in 2007 (Rosamond et al., 2007). Around 80–85% of strokes are ischemic and 15–20% of strokes are hemorrhagic. Over the past three decades neuroimaging methods such as computed tomography (CT) and magnetic resonance imaging (MRI) have enormously improved the rapid and accurate diagnosis of ischemic and hemorrhagic stroke (Figure 31.1). More recently, non-invasive vascular imaging methods such as CT angiography (CTA) and MR angiography (MRA) have proven invaluable for the detection of vascular stenoses in the carotid arteries. But the therapeutics of stroke has lagged behind.

Treatment approaches for ischemic stroke have largely focused on reperfusing the ischemic brain tissue—for example with the thrombolytic agent recombinant tissue plasminogen activator (rt-PA, The National Institute of Neurological Disorders and Stroke rt-PA Stroke Study Group, 1995)—and on neuronal protection, mainly from damage caused by excitotoxic amino acids such as glutamate. Over the past 15 years it has been increasingly appreciated that inflammation alone, or in combination with systemic immune system responses, may be an important contributing factor in stroke-related brain injury and stroke outcome, as well as in the development of atherosclerotic cerebrovascular disease. Elements of the inflammatory process may provide promising targets for the treatment of acute ischemic stroke and for vascular disease prevention.

As has been outlined in prior chapters, the immune system is responsible for host responses to infection, and responds in the same way to tissue injury occurring in the body, e.g., as

occurs in the brain after stroke. It has been appreciated from post-mortem studies for more than 50 years that leukocyte accumulation—i.e., presumably neutrophil polymorphs and macrophages but the white cell types were not stated in the early studies—in the infarcted brain tissue is a prominent feature of the progression of ischemic brain lesions, and this was thought to be primarily related to the phagocytosis of necrotic brain tissue (Garcia et al., 1994). Inflammation is now considered to actively modify the evolution and repair of ischemic lesions and to probably impact significantly on tissue and clinical outcome after stroke (Garcia, 1992). This stroke-related inflammation is characterized by cellular responses, by activation of immune, endothelial and glial cells, and by the secretion of cytokines and chemokines. Although still somewhat controversial, the current concept that has emerged is of a twofold impact: early on, inflammation appears to exacerbate ischemic and reperfusion injury after stroke, while later on, inflammatory cells may be actively involved in tissue repair and remodeling, and so play a beneficial role (Hallenbeck et al., 2005). Furthermore, exposure to brain antigens may sensitize peripheral leukocytes and it is possible that sensitized memory T cell lymphocytes may either be protective (if sensitized in low doses, resulting in tolerance) or lead to more aggressive immune responses to subsequent stroke (if highly sensitized from exposure to antigens in high doses). Brain-induced systemic inflammation may also increase patients' susceptibility to infections after stroke, most commonly pneumonia and urinary tract infections (Meisel et al., 2005). The role of inflammation in atherosclerotic cerebrovascular disease has also been increasingly recognized to the effect that atherosclerosis is no longer regarded as a disorder of lipid storage within blood vessels but now, primarily, as a disorder of chronic inflammation (Libby et al., 2002).

These changing concepts of the role of the immune system and inflammation in stroke and cerebrovascular disease have led to searches for new treatment and prevention strategies. This chapter will review the current state of knowledge about inflammation and the immune system in stroke and atherosclerosis and discuss potential therapeutic strategies.

FIGURE 31.1. Ischemic and hemorrhagic stroke. Computed tomography (CT) brain scans of two patients, one with ischemic stroke (left) and one with hemorrhagic stroke (right).

31.2. Immunity and the Central Nervous System

Under physiological conditions there is a small resident population of macrophages—microglia and perivascular macrophages—along with some roaming T cell lymphocytes in the central nervous system. However, most of the immune cells involved in inflammation after stroke are in fact derived from the systemic circulation.

31.2.1. Immune Surveillance and the Central Nervous System

The central nervous system has traditionally been considered to be a severely disadvantaged site for the elicitation of immune responses for the following reasons: (1) the blood brain barrier (BBB) which strictly regulates the passage of molecules and cells into the central nervous system; (2) the poorly developed lymphatic drainage (some cerebrospinal fluid drains into the cervical lymphatics); (3) the low levels of major histocompatibility complex (MHC) molecule expression on microglia, neurons and astrocytes; and (4) the absence of a specific antigen presenting cell type that is particularly important in the initiation of immune responses, the dendritic cell, which is derived from the hematopoietic monocytic cell lineage (Sedgwick, 1995; Karman et al., 2004).

However as stated above, there are some resident immune cells in the brain: these include the microglia, which are derived from the mesoderm and can be replenished from the bone marrow (in contrast to neurons and astrocytes which are ectoderm derived and only replenished in minute numbers). Unlike other tissue macrophages, microglia do not express MHC antigens until they become activated. Another resident

immune cell in the brain is the perivascular macrophage that appears to be important in antigen recognition (more so than microglia or neurons). It is also widely accepted that T cell lymphocytes perform surveillance functions in normal brain parenchyma: however, only activated T cells can cross the BBB and they enter the brain in smaller numbers than in other organs of the body. It appears that the entry of T cell lymphocytes is related to a roaming immune surveillance function, rather than being a targeted response to specific brain signaling (Hickey, 2001; Ransohoff et al., 2003). Unlike other organs there are very few resident mast cells in the brain and there are no resident neutrophils. Dendritic cells, although not present in brain parenchyma, are present in the choroid plexus and the meninges; these sites could potentially provide a source of immediate responders after acute brain ischemia, although this has yet to be demonstrated (Karman et al., 2004). From being considered a so-called “immune privileged” site (i.e., severely disadvantaged), the central nervous system is now regarded as an “immunologically specialized” site.

31.2.2. Innate and Adaptive Immunity

After stroke the majority of immune cells in the brain are derived from the circulating blood. Activation of the systemic immune system includes both the innate and adaptive immune systems. The innate immune system is characterized by the immediacy of its response and the non-specificity of its response, and it does not confer long-lasting or protective immunity. Cells of the innate immune system include circulating polymorphonuclear cells (mainly neutrophils), monocyte-macrophages, and natural killer (NK) lymphocytes. The adaptive immune system is specifically characterized by its ability to alter receptor expression and cellular functions when encountering new antigens, whether self or foreign; functions include

cell-mediated immunity, humoral immunity, immune response regulation, memory and immunologic tolerance. Cells of the adaptive immune system include T cell lymphocytes—helper T (Th) cells (generally CD4⁺) and cytotoxic T cells (generally CD8⁺)—and B cell lymphocytes. Recent evidence suggests a role of NK cells in memory (Hamerman et al., 2005). After antigenic activation, CD4⁺ T cells can be differentiated into at least three subsets: Th1 (involved in cell-mediated immunity and which secrete pro-inflammatory cytokines such as gamma-interferon [γ -IFN], interleukin-2 [IL-2] and lymphotoxin), Th2 (which promote humoral immunity and secrete anti-inflammatory cytokines such as IL-4 and IL-10) and regulatory T cells (e.g., CD4⁺ CD25⁺, which secrete transforming growth factor-beta [TGF- β] and IL-10).

31.3. Ischemic Stroke and Inflammation

Ischemic strokes account for around 80–85% of all strokes and are caused by arterial vascular occlusions; rarely occlusion in the cerebral venous system may result in ischemic and/or hemorrhagic stroke. Arterial occlusions resulting from cerebral embolism are the most common causes of ischemic strokes, and by about one week after stroke as many as 70–90% of occlusions will have spontaneously recanalized. Emboli typically originate from atherosclerotic stenoses in the internal carotid artery or from sources in the heart such as clots in the left atrium or the left ventricle. Hypertension-induced vascular disease of the small perforating intracerebral arteries is a common cause of lacunar strokes. A classification of the major stroke subtypes is shown in Table 31.1.

Immediately after the onset of focal brain ischemia, oxygen and glucose deprivation result in loss of adenosine triphosphate (ATP), loss of maintenance of normal ion channels and neuronal depolarization (Wahlgren and Ahmed, 2004) as evidenced by calcium and sodium influx into the cells,

TABLE 31.1. Classification of major stroke subtypes.

	Subtypes	Common causes
Ischemic (80–85%)	Large artery	Carotid artery stenosis
	Cardioembolic	Atrial fibrillation, ventricular clot
	Small vessel disease (i.e., lacune)	Lipohyalinosis of penetrating intracranial arteries
	Other determined Undetermined	Blood dyscrasias
Hemorrhagic (15–20%)	Intracerebral	Hypertension
		Amyloid angiopathy
	Subarachnoid	Aneurysm Arteriovenous malformation

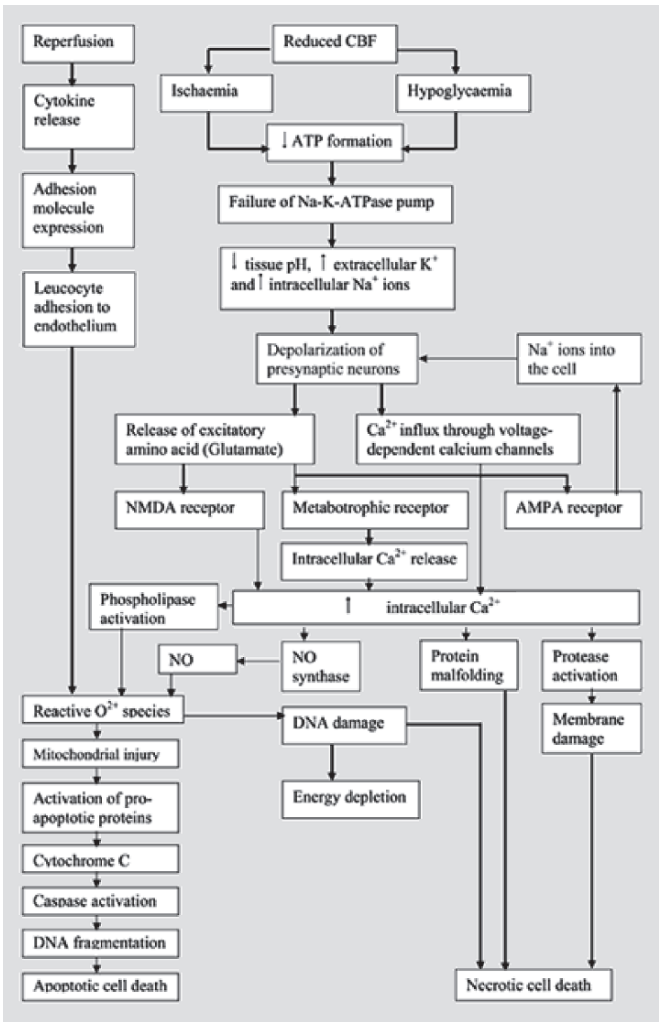

FIGURE 31.2 Cascade of molecular events during focal cerebral ischemia. Cascade of molecular events during ischemia and reperfusion injury. During cerebral ischemia, a series of biochemical events occur that causes depolarization, activation of voltage-operated calcium channels and excessive release of excitatory amino acids, especially glutamate. Activation of glutamate receptors leads to a further increase in intracellular calcium, activation of intracellular enzymes and neuronal death. Successive exploration of this complex pathophysiology has resulted in the development of a great number of candidates for neuroprotective intervention. Many of these candidates have proven to be efficacious in animal models, but so far no trial in stroke patients has confirmed a benefit on primary endpoint measures. CBF = Cerebral blood flow; ATP = adenosine triphosphate; AMPA = *D*-amino-3-hydroxyl-5-ethyl-4-isoxazole propionate; NMDA = *N*-methyl-*D*-aspartate; NO = nitric oxide. Reproduced from Wahlgren NG, Ahmed N (2004) *Neuroprotection in cerebral ischaemia: facts and fancies—the need for new approaches. Cerebrovasc Dis, 17 Suppl 1:153–166* (permission from S. Karger AG, Medical and Scientific Publishers).

generation of oxygen free radicals and breakdown of membranes. The cascade of molecular events is shown in Figure 31.2. Brain tissue may be viable for only minutes to 1 h in the core of the resulting infarct, where the blood flow is of

the order of 0–10 ml/100 g brain tissue/minute. The ischemic penumbra is the zone of potentially viable tissue surrounding the infarct core; this tissue is nourished in part by collateral blood vessels and may be viable for up to 3–6 h if the perfusion is restored in time. Inflammation is now believed to contribute to brain injury in both the core and the ischemic penumbra, and is believed to be particularly hazardous after reperfusion (after spontaneous arterial recanalization or after rt-PA therapy). Following the return of the blood flow and oxygen the marked increase in oxidative-reduction reactions can lead to the brain's antioxidant systems becoming overwhelmed. Excess oxygen free radicals are generated which damage cerebral tissue directly and through the activation of apoptotic and necrotic cell signaling pathways (Wahlgren and Ahmed, 2004; Ding and Clark, 2006). Neutrophil polymorphs and macrophages exacerbate to reperfusion injury through the release of inflammatory molecules (e.g., pro-inflammatory cytokines) and free radical species.

The current state of knowledge comes from studies in experimental stroke models, from human post-mortem studies and clinical studies. Early magnetic resonance imaging studies showed a correlation between elevated lactate and macrophage brain infiltration. This was identified at autopsy neuropathological examination within a week of the lactate determinations (Petroff et al., 1992). Moreover, elevated lactate also correlated with reduced N-acetylaspartate concentrations by magnetic resonance spectroscopy and with the presence of sheets of foamy macrophages within infarcts. In additional clinical neuroimaging studies employing positron emission tomography (using PK11195 which binds to peripheral benzodiazepine receptors expressed on activated microglia, Figure 31.3, Pappata et al., 2000; Gerhard et al., 2000), single photon emission computed tomography (using indium-111 to detect neutrophil recruitment, Price et al., 2004) and, most recently, magnetic resonance imaging using ultra-small superparamagnetic iron oxide nanoparticles all have demonstrated macrophage infiltration during stroke (Saleh et al., 2004).

31.3.1. Involvement of Immune Cells

The first immune responders after focal cerebral ischemia are the brain microglia. As mentioned above, in the normal brain, microglia are quiescent or inactive, but after an injury, these cells undergo a dramatic change, altering their appearance, and migrating to the site of the damage to help clear away and clean up dead and dying cells and cell debris. Microglia produce cytokines, which trigger astrocytes and cells of the immune system to respond to the injury site (Vilhardt, 2005).

Stroke-related inflammation in the brain appears to largely result from a selective migration and infiltration of systemic (i.e., circulating) leukocytes to the focus of cerebral ischemia. These cells are predominantly those of the innate immune system, at least initially. Activated neutrophil polymorphs begin to infiltrate as early as 4 h after stroke, initially being

located at the edges of the infarct, and subsequently in the infarct core. The time course of neutrophil polymorph infiltration is depicted in Figure 31.4: the neutrophil response may be largely completed by 4–7 days in humans (Nilupul Perera et al., 2006). The infiltration of neutrophils overlaps with and is followed by a more prolonged and sustained infiltration of blood-borne monocytes, which become macrophages once they have entered the brain. This starts within the first 24–48 h and may persist for days to weeks to even months. It is not always possible to distinguish between blood-borne macrophages and activated microglia because of similar antigen expression (e.g., CD163, a marker of activated macrophages, is expressed on both). It was noted in early post-mortem studies that the degree of leukocyte infiltration was not always uniform. This cellular inflammation is believed to exacerbate brain injury through the secretion of pro-inflammatory cytokines and through clogging of blood vessels, leading to a no-reflow phenomenon.

Although not commonly recognized, there has been indirect evidence for some years that cells from the adaptive immune system too may play an important role early on in ischemic stroke (Hallenbeck et al., 2005; Schroeter et al., 1994; Becker et al., 2001, 2003). CD8⁺ lymphocytes have been found in the brain in the first few days in some post-mortem studies and blockade of adaptive immune processes may impact significantly on stroke outcomes. Recently it has been reported in an experimental mouse stroke model (Yilmaz et al., 2006) that CD4⁺ and CD8⁺ T lymphocytes and γ -IFN may play important roles in the exacerbation of ischemic reperfusion injury as early as 5 h after stroke. In this study CD4⁺ and CD8⁺ T cells and γ -IFN caused the cerebral microvasculature to assume a pro-inflammatory and pro-thrombotic phenotype (as evidenced by increased leukocyte and platelet adhesion to the endothelium). It is possible that lymphocytes may act indirectly, by activating other circulating blood cells and/or extravascular cells such as resident macrophages in the brain. Alternatively lymphocytes may act directly on brain tissue: cytotoxic CD8⁺ T-cells may induce brain injury through molecules released from their cytotoxic granules. CD4⁺ Th1 cells, which secrete pro-inflammatory cytokines, including interleukin-2 (IL-2), IL-12, γ -IFN and tumor necrosis factor (TNF), may play a key role in the pathogenesis of stroke, whereas CD4⁺ Th2 cells may play a protective role through anti-inflammatory cytokines such as IL-4, IL-5, IL-10, and IL-13. Evidence suggests that T cell lymphocytes are likely to be key players in the overall regulation of the immune response.

31.3.2. Molecular Mediators of Inflammation

Inflammatory molecules include adhesion molecules, chemokines and cytokines, many of which are up-regulated in acute cerebral ischemia and contribute to the inflammatory process. The release of pro-inflammatory cytokines is a direct consequence of the ionic imbalances and free calcium accumulation that lead to the release of free fatty acids and other

FIGURE 31.3. [11C]PK11195 positron emission tomography (PET) brain imaging in ischemic stroke. [11C]PK11195 is a peripheral benzodiazepine receptor marker expressed on activated microglia/macrophages. [11C]PK11195 positron emission tomography (PET) and T1 weighted NMR of an 87-year-old patient with a left middle cerebral artery territory infarct. The top row shows the images obtained at 5 days and the bottom row the images at 13 days. The T1 weighted MRI is shown in the first column, the PET image in the second column and the co-registered MRI-PET in the third column. Green indicates low receptor binding and red/yellow and white high binding. After 5 days there is only a small degree of PK-binding in the left MCA territory, especially in the temporal lobe, and it is much more pronounced after 13 days. At this time the area of increased binding seems to exceed the area of signal change in the NMR occipitally. Adapted from Gerhard A, Neumaier B, Elitok E, Glatting G, Ries V, Tomczak R, Ludolph AC, Reske SN (2000). In vivo imaging of activated microglia using [11C]PK11195 and positron emission tomography in patients after ischemic stroke. *Neuroreport*, 11:2957–2960. FIGURE 31.4. Time course of cellular and molecular activation following stroke. Diagrammatic representation of the time course of cellular activation (PNL, polymorphonuclear leukocytes; Mφ, macrophages) and inflammatory molecular expression (GM, granulocyte and monocyte colony-stimulating factor; ICAM, soluble intercellular adhesion molecule-1; VCAM, soluble vascular cell adhesion molecule-1; TNF-α, tumor necrosis factor α; IL-1β, interleukin 1β; IL-6, interleukin 6; IL-8, interleukin 8; IL-10, interleukin 10) in human brain, cerebrospinal fluid (CSF) and blood after stroke. Reproduced from Nilupul Perera M, Ma HK, Arakawa S, Howells DW, Markus R, Rowe CC, Donnan GA (2006). *Inflammation following stroke*. *J Clin Neurosci*, 13:1–8 (with permission from Elsevier).

pro-inflammatory lipid metabolites. These metabolites promote the expression and release of IL-1 β and TNF initially from activated microglia; these cytokines then lead to the production of other pro-inflammatory cytokines (e.g., IL-6, IL-8), the activation and infiltration of leukocytes, and the production of anti-inflammatory cytokines (including IL-4 and IL-10), which produces a negative feedback on the cascade. Adhesion molecules include intercellular adhesion molecule (ICAM), vascular cell adhesion molecule (VCAM), and E-selectin, which are expressed on activated endothelial cells during inflammation. Monocyte chemoattractant protein-1 is a chemokine that promotes infiltration of monocytes into the ischemic brain focus.

Other molecular mediators include complement, a host defense system made up of plasma proteins, which identifies pathogens and injured cells, recruits inflammatory cells and induces cell lysis. Early components in the classical, lectin or alternative complement pathways are believed to initiate the cascade leading to microglial activation and the activation and infiltration of blood-borne neutrophils and monocytes. The complement pathway may be activated by ICAM expression on endothelial cells. The matrix metalloproteinases (MMPs) are proteolytic proteins involved in the inflammatory response to stroke, one of the most prominent being MMP-9 which promotes degradation of the extracellular matrix proteins and increases the permeability of the BBB. Myeloperoxidase, an enzyme largely derived from neutrophils but also from some monocytes, catalyzes a number of reactions that generate oxygen free radicals (e.g., superoxide and hydroxyl radicals), particularly after reperfusion. The time course of cytokine changes in the human brain, cerebrospinal fluid and peripheral blood is shown in Figure 31.4 (Nilupul Perera et al., 2006).

31.3.3. Migration of Immune Cells Across the Blood Brain Barrier

The BBB provides the interface between the blood and brain and consists of endothelial cells held together by tight junctions ("zonula occludens"), the matrix containing basal lamina and the astrocyte foot processes that surround 90% or more of the capillary wall. Normally the BBB is impermeable to most cells, and to large and hydrophobic molecules. Leukocyte infiltration after ischemic stroke is dependent on the expression of adhesion molecules on leukocytes and endothelial cells (Barone and Feuerstein 1999). Neutrophils, monocytes and lymphocytes express β 2-integrin (i.e., CD11b/CD18), an adhesion molecule that binds to ICAM-1 and ICAM-2 expressed on activated endothelial cells. Lymphocytes and monocytes also express another group of adhesion molecules, α 4-integrins, which attach to VCAM-1 on endothelial cells (Figure 31.5). Later on, starting within the first 24 h and going on for several weeks, the BBB breaks down and the passage of immune cells is less impeded.

Blockade of neutrophil infiltration in experimental stroke models, through inhibition of adhesion molecules (ICAM-1,

E-selectin [only expressed on activated endothelium], P-selectin) and macrophage-1 antigen (which facilitates leukocyte phagocytosis in addition to leukocyte adhesion and transendothelial migration), has been shown to reduce infarct size (Jiang et al., 1995; Mackay et al., 1996). Furthermore, blockade acutely of α 4-integrin (Becker et al., 2001) and CD44, a cell surface glycoprotein involved in cell/cell and cell/matrix interactions (Wang et al., 2002) also reduced infarct size to a similar degree, indicating that early infiltration of mononuclear cells (monocytes and lymphocytes) probably has a more significant impact on tissue outcome early after stroke than may have previously been appreciated.

The concept of the "neurovascular unit"—a functional entity comprising neurons, astrocytes, smooth muscle cells and endothelial cells—has now emerged and it is appreciated that this coordinated unit plays a key role in the hemodynamic response to alterations in brain function and activity. Disruption of this regulatory network occurs after stroke and it is now believed that efforts at neuroprotection should target the entire unit, not just neurons (del Zoppo, 2006).

31.3.4. Effects of Ischemic Stroke on the Systemic Immune System

Stroke induces an acute stress response—i.e., over-activation of the sympathetic nervous system and increased corticosteroid levels (with resultant neutrophilia and lymphocytopenia). This in turn leads to depressed immunity and altered immune responses during the acute phase of stroke and may predispose patients to infections, particularly pneumonia, which is the commonest cause of mortality after the first few days of stroke (Meisel et al., 2005). In the clinical setting, increased total white cell counts and neutrophilia, which correlate with infarct size, are independently associated with worse outcome after stroke. Recently a massive and early activation of the systemic immune system has been shown to occur also in experimental stroke (Offner et al., 2006).

Exposure to local and leaking brain antigens in ischemic brain—such as myelin basic protein—has been shown to sensitize [in high doses] and tolerize [in low doses] peripheral leukocytes (presumably lymphocytes, Becker et al., 2003; Alvord et al., 1974; Youngchaiyud et al., 1974). The functional consequences are not clear but it is possible that such exposure may lead to recurrent strokes or to a more intense inflammatory response in subsequent strokes, or alternatively to tolerance. It has also been suggested that ischemic preconditioning, for which there is evidence in clinical stroke, may be immunologically mediated (i.e., after a recent transient ischemic attack (TIA) it is claimed that patients may have less severe strokes but this is still controversial, Kariko et al., 2004).

Recently, elevated CD4⁺ CD28⁻ T cell counts have been shown to be associated with worse outcome after ischemic stroke (Nadareishvili et al., 2004). This pro-inflammatory T cell subset is characterized by longevity, resistance to

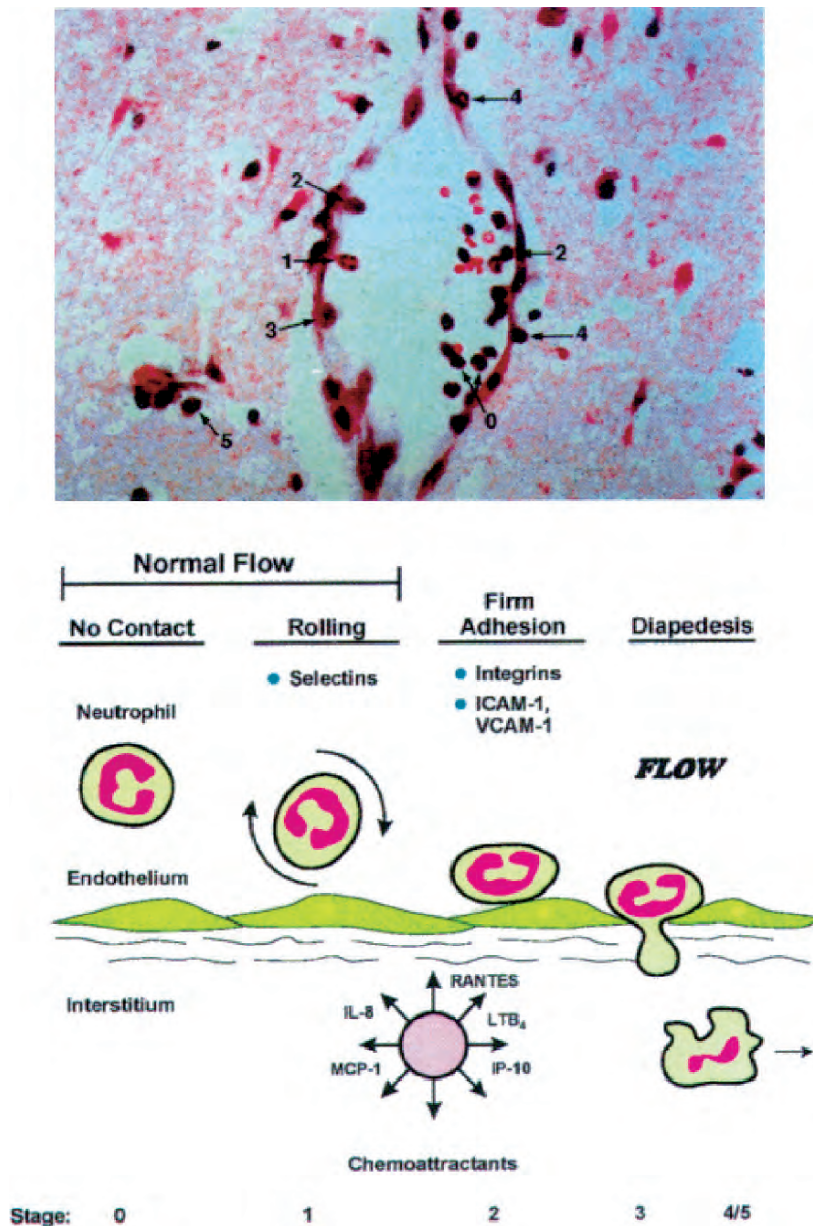

FIGURE 31.5. Leukocyte migration into focally ischemic brain. Histologic and schematic representations of changes in leukocyte behavior in the brain microvessels after focal ischemia. Shortly (within 1–6 h) after experimental stroke, many of the leukocytes, primarily neutrophils, in the ischemic tissue vessels are adherent to the post-capillary venule and capillary walls. This can modify and exacerbate the decreased blood flow occurring in the already ischemic brain. Then, these neutrophils can find their way outside the vascular walls into the focal ischemic cortex over the next 6–24 h. Macrophages move into the brain later (i.e., over 1–5 days) and significantly accumulate in the infarcted brain. These changes in leukocyte behavior are mediated by increased brain inflammatory cytokine, adhesion molecule(s), and chemokine expression in the ischemic/injured brain. *Reproduced from ref Barone FC, Feuerstein GZ. Inflammatory mediators and stroke: new opportunities for novel therapeutics. J Cereb Blood Flow Metab 1999; 19: 819–834. With permission from Nature.*

apoptosis and secretion of high levels of γ -IFN. Patients with CD4⁺ CD28⁻ levels >8% (normally present in <1% of CD4⁺ cells) during the first 48 h of stroke had a 6-fold increase in dying or developing a recurrent stroke during the following year. A notable finding was that patients with prior stroke had higher levels of these cells, raising the possibility that this

population of T cells, already sensitized to brain antigens, contributed to a greater pro-inflammatory reaction to the new stroke. Elevated levels of this pro-inflammatory T cell subset have also been associated with the development of unstable atherosclerotic plaques. With improved typing of lymphocytes it is possible, and even likely, that different functional classes

of lymphocytes present prior to or at the time of stroke and which could affect the evolution of ischemic lesions and outcome, will be recognized.

31.3.5. Tissue Repair and Recovery After Ischemic Stroke

The role played by the immune system in the acute phase of ischemic stroke so far appears largely to be unfavorable. A positive role for the immune system may be in tissue remodeling and repair, and the recovery of function days to weeks after stroke. The blood-borne mononuclear cells that have invaded the focally ischemic brain have been shown to up-regulate the expression of neurotrophic and other growth factor genes (e.g., those involved in angiogenesis, Barone and Feuerstein, 1999; Dirnagl et al., 1999). Resident-activated glial cells can also protect cells by facilitating repair and remodeling, and increasing neuronal plasticity, thereby facilitating the recovery of function for the remaining viable neurons and tissue (Figure 31.6). Hematopoietic stem cells may be involved in tissue repair and recovery after stroke, through the generation of microglia and macrophages, and possibly even new neurons (Brazelton et al., 2000; Paczkowska et al., 2005).

31.4. Hemorrhagic Stroke and Inflammation

Hemorrhagic strokes account for 15–20% of all strokes (Figure 31.1). Rupture of a blood vessel into the brain parenchyma results in an intracerebral hemorrhage (ICH);

this is commonly caused by hypertension-induced vascular disease of the small perforating intracranial arteries. Chronic hypertension leads to intimal hyperplasia with hyalinosis in the small vessel wall; this predisposes to focal necrosis, causing breaks in the wall of the vessel and “pseudoaneurysms.” Another cause of intracerebral hemorrhage is amyloid angiopathy. Rupture of a vessel into the subarachnoid space results in a subarachnoid hemorrhage; this most commonly results from rupture of a brain aneurysm or an arteriovenous malformation (Table 31.1).

After ICH mechanical brain injury results from tissue destruction and increased intracranial pressure from the mass effect of the hematoma occurring within the closed skull. After ICH, as occurs after ischemic stroke there is also an inflammatory reaction, consisting of an initial microglial response followed by an influx of systemic neutrophils and other white blood cells, up-regulation of molecules related to the adhesion of white blood cells to the endothelium, their migration across the BBB and their direction to the site of injury (Gong et al., 2000). It also appears that the hematoma itself actively induces pathways that lead to brain injury, brain edema and worsening of the neurological outcome. These pathways include thrombin produced during clot formation and iron released from hemoglobin via the action of heme oxygenase, along with the influx of neutrophils, microglial activation and complement activation that may exacerbate tissue injury in the peri-hematoma region. It has been hypothesized that this may be a protective response to small hematomas but may be deleterious in large hematomas (Keep et al., 2005); up-regulation of these above factors may be an evolutionary adaptation to limit brain injury during small hematomas (microbleeds),

FIGURE 31.6. Brain recovery and repair after stroke. After initiation of brain injury various neurodestructive and neuroprotective genes are expressed. Neurodestructive gene expression (e.g., primarily those inflammatory cytokines, adhesion molecules, chemokines, and inflammatory proteins such as inducible NOS and metalloproteinases) can drive brain inflammation and necrotic/apoptotic cell death. Neuroprotective gene expression includes neurotrophic and growth factors from circulating mononuclear cells that have infiltrated into damaged tissue. In addition, resident-activated glial cells can also protect cells/tissue by facilitating repair and remodeling, and/or increasing neuronal plasticity and thereby facilitating the recovery of function for the remaining viable neurons/tissue. *Reproduced from Barone FC, Feuerstein GZ. Inflammatory mediators and stroke: new opportunities for novel therapeutics. J Cereb Blood Flow Metab 1999; 19: 819–834. With permission from Nature.*

with low levels of these factors being protective but high levels being excessively harmful (as may occur in large hematomas). In experimental models anti-inflammatory drugs such as COX-2 inhibitors, tacrolimus and fucoidan may reduce peri-hematoma inflammation and improve outcome (Nilupul Perera et al., 2006). Administration of the lipid-lowering drug atorvastatin was also associated with improved outcome after experimental ICH through modulation of inflammation in the peri-hematoma region (Jung et al., 2004).

After subarachnoid hemorrhage vasospasm is a common complication that results from irritation of the intracranial vasculature by subarachnoid blood. Vasospasm may lead to delayed cerebral ischemia and ischemic strokes, up to several weeks after the initial hemorrhage. There is preliminary evidence that inflammation plays a role in vasospasm after subarachnoid hemorrhage (Nilupul Perera et al., 2006; Clatterbuck et al., 2003), and anti-inflammatory strategies have been shown to prevent vasospasm in experimental stroke models (Nilupul Perera et al., 2006).

31.5. Atherosclerotic Cerebrovascular Disease and Inflammation

The study of cerebrovascular disease has advanced markedly in recent years with advances in non-invasive imaging methods such as MR angiography and CT angiography as well as an improved understanding of the immune system in the pathogenesis of atherosclerosis. Atherosclerotic cerebrovascular disease is a common cause of strokes and shows a predilection for sites such as the bifurcation of the common carotid artery into the internal and external carotid arteries and the aortic arch and the major intracranial arteries such as the basilar artery and the middle cerebral arteries. Occlusive atherosclerotic vascular disease of these large extracranial arteries is responsible for as many as 20–30% of ischemic strokes and intracranial steno-occlusive disease causes around 5–10% of ischemic strokes.

Atherosclerosis is characterized by the formation of plaques within the innermost layer of artery walls. It has traditionally been regarded as a disorder of lipid storage but is now regarded as a chronic inflammatory disorder. The plaque commences with the deposition of cholesterol-containing lipoproteins in the vessel wall. The first inflammatory cells involved are believed to be circulating monocytes (rather than neutrophil polymorphs). These migrate across the endothelial lining from the blood or from the lymphatics and develop into tissue macrophages or into dendritic cells. The macrophages (“foam cells”) accumulate cholesterol in the artery wall. The resulting fatty streaks commence as early as the late teen years or the early 20s and may regress or progress throughout life. Lesions are typically asymptomatic, at least initially. Many fatty streaks develop into atheromatous plaques that contain extracellular debris and cholesterol. A fibrous cap is formed over the lipid-containing plaque by smooth muscle cells from

the arterial wall and possibly from blood-derived progenitor cells. The collagen stabilizes the lesion and prevents debris, lipids and pro-coagulant material from reaching the bloodstream (Hallenbeck et al., 2005, Figure 31.7). Pro-inflammatory lymphocytes (i.e., CD4⁺ Th1 cells) also contribute to and may accelerate atherosclerotic plaque formation (Libby et al., 2002). CD4⁺ CD28⁻ cells (mentioned previously) are a rare subset of CD4⁺ T cells that are long-lived, secrete high levels of γ -IFN and are directly cytotoxic. These cells preferentially infiltrate unstable plaques and contribute to increased endothelial cell lysis in patients with acute coronary syndromes (Nakajima et al., 2002). Naturally arising regulatory T cells (CD4⁺ CD25⁺) have recently been shown to be potent inhibitors of the development of atherosclerosis in several mice models and may be a promising target for vascular disease prevention (Ait-Oufella et al., 2006). It has also been suggested that common infections may be associated in the pathogenesis of atherosclerosis. Specific organisms that have been studied include *Chlamydia pneumoniae*, herpes viruses, *human immunodeficiency virus*, *Helicobacter pylori*, and organisms associated with periodontal infections; however definitive proof of causal associations are lacking.

The atheromatous plaque grows silently for years or even decades without producing clinical symptoms. However, trace amounts of pro-inflammatory cytokines released from cells within the plaque, including IL-6, reach the bloodstream and stimulate C-reactive protein (CRP) secretion by the liver. CRP can be detected in the peripheral blood and is an independent marker of risk for myocardial infarction and probably for stroke in healthy individuals. Atherosclerotic plaques precipitate ischemic strokes by rupturing, leading to superimposed thrombus formation and embolism. They may also lead to strokes if the narrowing becomes particularly severe, >50%. The risk of stroke is greater with the greater degrees of narrowing as there is also associated hemodynamic insufficiency. Conventional angiographic techniques and non-invasive modalities (ultrasound, MRA, CTA) are used to detect occlusive arterial disease, and in the case of stroke prevention a narrowing of $\geq 50\%$ of the internal carotid artery is used in decision-making for referral of patients for carotid endarterectomy.

Certain plaques are particularly prone to rupture. These “vulnerable plaques” contain abundant inflammatory cells and have thin collagen caps. The atheroma’s vulnerability to rupture is correlated with higher cellular infiltrates of macrophages and activated T cells. In symptomatic carotid artery plaques elevated ICAM-1 expression (relative to asymptomatic plaques) has been found and the ICAM-1 expression was greatest in the high-grade region of the plaque. Vulnerable plaques are also not necessarily the largest plaques, particularly in patients with coronary artery disease, and current angiographic methods are of limited value in their recognition. However, new MRI methods using novel contrast agents are now being used to better study the features of vulnerable plaques.

FIGURE 31.7. Inflammation and atherosclerosis. Participation of inflammation in all stages of atherosclerosis. **A:** Leukocyte (i.e., monocyte) recruitment to the nascent atherosclerotic lesion. Blood leukocytes adhere poorly to the normal endothelium. When the endothelial monolayer becomes inflamed, it expresses adhesion molecules that bind cognate ligands on leukocytes. Selectins mediate a rolling, or saltatory, interaction with the inflamed luminal endothelium. Integrins mediate firmer attachment. Pro-inflammatory cytokines expressed within atheroma provide a chemotactic stimulus to the adherent leukocytes, directing their migration into the intima. Inflammatory mediators such as macrophage colony stimulating factor (M-CSF) can augment expression of macrophage scavenger receptors leading to uptake of modified lipoprotein particles and formation of lipid-laden macrophages. M-CSF and other mediators produced in plaques can promote the replication of macrophages within the intima as well. **B:** T lymphocytes join macrophages in the intima during lesion evolution. These leukocytes, as well as resident vascular wall cells, secrete cytokines and growth factors that can promote the migration and proliferation of smooth muscle cells (SMCs). Medial SMCs express specialized enzymes that can degrade the elastin and collagen in response to inflammatory stimulation. This degradation of the arterial extracellular matrix permits the penetration of the SMCs through the elastic laminae and collagenous matrix of the growing plaque. **C:** Ultimately, inflammatory mediators can inhibit collagen synthesis and evoke the expression of collagenases by foam cells within the intimal lesion. These alterations in extracellular matrix metabolism thin the fibrous cap, rendering it weak and susceptible to rupture. Cross-talk between T lymphocytes and macrophages heightens the expression of the potent procoagulant tissue factor. Thus, when the plaque ruptures, as shown here, the tissue factor induced by the inflammatory signaling triggers the thrombus that causes most acute complications of atherosclerosis. (Reproduced from ref [7]: Libby P, Ridker PM, Maseri A. Inflammation and atherosclerosis. *Circulation* 2002; 105: 1135–1143. Permission from Lippincott, Williams & Wilkins).

31.6. Risk Factors for Stroke

As mentioned above, atherosclerotic vascular disease is a common cause of ischemic stroke and also predisposes patients to coronary artery disease, itself a risk factor for stroke. Vascular disease also increases with age and is increased in patients with hypertension, diabetes, a smoking history and hyperlipidemia. Hypertension is the major risk factor for hemorrhagic stroke. Common risk factors for stroke and cerebrovascular disease are listed in Table 31.2. The “metabolic syndrome” is a cluster of risk factors (truncal obesity, hyperglycemia, hypertriglyceridemia, hypertension and low HDL-cholesterol) associated with increased cardiovascular disease risk. Some immune and inflammatory risk factors may include recent infection that increases the risk of stroke to a modest degree and the possible mechanisms for this are being investigated. Periodontal disease, another factor shown to be independently associated with stroke and coronary artery disease, is believed to be associated with chronic inflammation and endothelial dysfunction (Janket et al., 2003). Lipoprotein associated phospholipase A₂ (a pro-inflammatory enzyme associated with low density lipoprotein) is approved by the Food and Drug Administration as a risk marker for stroke and coronary artery disease. Other inflammatory markers in the blood are showing promise as independent risk factors; these include elevated plasma levels of high sensitivity-CRP, IL-6 and the total white blood cell count (Ballantyne et al., 2005).

31.7. Therapeutic Neuroimmune Pharmacological Intervention

31.7.1. Treatment of Ischemic Stroke

As well as other strategies in the treatment and prevention of stroke the improved knowledge of the role of inflammation and the immune system in stroke and cerebrovascular disease has opened the door for research using *immunomodulatory* approaches in the treatment and prevention of stroke. There is only one Food and Drug Administration (FDA) approved treatment for ischemic stroke, the thrombolytic agent rt-PA that enhances brain reperfusion. Neuroprotective trials have been disappointing, with NXY-059—a free radical scavenger—being the latest casualty (Lees et al., 2006; del Zoppo, 2006; <http://www.astrazeneca.com>, 2007). It is of note that a major limitation of hypothermia therapy for stroke, another form of neuroprotective therapy, has been the excess rate of pneumonic complications that has precluded its use, especially in the elderly.

Immune modulation approaches would seem to be worthwhile pursuing based on the significance of the immune response on tissue and clinical outcomes after stroke. To date, therapeutic strategies for acute ischemic stroke have focused on preventing the recruitment and trafficking of neutrophils into ischemic lesions through inhibition of cellular adhesion molecules, however without success (Enlimomab Acute Stroke Trial Investigators, 2001). Enlimomab, a murine monoclonal antibody against ICAM-1, administered within 6 h of

Use of COX-2 inhibitors
Elevated lipoprotein associated phospholipase A₂
Elevated IL-6 (precursor of CRP)
Elevated hsCRP
Elevated total white cell count

onset and continued for 5 days, led to worse stroke outcome: the antibody itself elicited a strong and adverse inflammatory reaction (Furuya et al., 2001). UK-279,276, an antibody that binds selectively to the CD11b/CD18 integrin on neutrophils was not effective in the Acute Stroke Therapy by Inhibition of Neutrophils (ASTIN) study (Krams et al., 2003). It is possible that partial inhibition of neutrophils may be more effective than complete blockade.

Other *immune modulatory* approaches could theoretically include leukocyte-depleting strategies (not appropriate for the clinical population) and general strategies aimed at suppressing immune function (e.g., steroid treatment): these have not proven to be effective in stroke and increase the risk of secondary infection. The antibiotic agent doxycycline appears to reduce leukocyte adhesion and was found to be beneficial in a temporary occlusion experimental stroke model, but has not so far been tested in the clinical setting (Clark et al., 1994). Recombinant human interferon beta-1a (IFN-b1a) is an FDA approved treatment for patients with relapsing remitting multiple sclerosis. IFN-b1a inhibits pro-inflammatory cytokines and prevents BBB disruption and is currently being studied in ischemic stroke in a phase 1 safety study. This agent could lessen reperfusion injury after stroke (and possibly hemorrhagic transformation of infarcts which can be a complication of rt-PA therapy). It too has been noted in a number of observational studies that patients who are taking a statin before a stroke have a better outcome than those who are not (Yoon et al., 2004). It has been proposed that, apart from cholesterol-lowering, statins work through other mechanisms that include *immune modulation* (decreased inflammation), decreased oxidative stress, inhibition of the thrombogenic response and increased atherosclerotic plaque stability. In experimental

stroke models statin administration has resulted in reduced size of brain infarcts (Kawashima et al., 2003).

31.7.2. Treatment of Hemorrhagic Stroke

There are few proven treatments for intracerebral hemorrhage, the main management issue being strict control of hypertension. Surgical evacuation is usually reserved for cerebellar hematomas, which show a mass effect (as clinically evidenced by a declining level of consciousness). The coagulation factor Factor VIIa did show some initial promise in phase 2 studies (Mayer et al., 2005) but was recently abandoned (<http://www.novonordisk.com>, 2007). In terms of *immune modulation*, anti-inflammatory drugs such as COX-2 inhibitors, tacrolimus and fucoidan may reduce peri-hematoma inflammation and improve outcome in experimental stroke models (Nilupul Perera et al., 2006). Administration of the lipid-lowering drug atorvastatin has also been associated with improved outcome after experimental intracerebral hemorrhage, perhaps in part through modulation of inflammation in the peri-hematoma region (Jung et al., 2004).

For subarachnoid hemorrhage surgical clipping of the causative aneurysm or resection of the arteriovenous malformation is the mainstay of treatment. Endovascular coiling of the aneurysm can also be performed. Post-operative infection (either brain or respiratory) is an uncommon complication and not believed to be any more common than after other invasive surgical procedures. Hypervolemic-hemodilution and hypertensive (HHH) therapy is used to prevent spasm. There may be a role for anti-inflammatory measures for the prevention of vasospasm and delayed cerebral ischemia, as shown in a recent pilot study of patients treated with statins (Lynch et al., 2005).

31.7.3. Primary and Secondary Prevention of Stroke

Apart from surgical and interventional therapy of occlusive carotid artery disease, the major approach to preventing vascular disease and subsequent stroke is to pay close attention to the control of modifiable risk factors such as hypertension, smoking, diabetes, and hypercholesterolemia. Coumadin, an anticoagulant, is effective for the primary and secondary prevention of stroke in patients with atrial fibrillation. Aspirin, clopidogrel, and the combination of aspirin and dipyridamole have been proven to be effective for secondary stroke prevention along with the antihypertensive combination of indapamide and perindopril.

In terms of vascular disease prevention, inducing mucosal tolerance to E-selectin may prevent ischemic and hemorrhagic strokes, as shown in an experimental stroke study: low dose exposure to E-selectin is believed to work by diverting the immune response towards a Th2 (anti-inflammatory) response (Takeda et al., 2002). A clinical trial is planned of this agent for secondary stroke prevention. Also, immune modulation using naturally arising regulatory T cells (CD4⁺ CD25⁺) may

be a promising approach for vascular disease prevention (Ait-Oufella et al., 2006).

Statins have an important role in primary and secondary stroke prevention and possibly work, at least in part as stated previously, by *immune modulation*. The reduction in vascular events with statin use correlates with increased degrees of lowering of the inflammatory marker hsCRP, and is independent of the degree of lipid-lowering. Statins have been shown to modulate gene expression in macrophages *in vitro* (Llaverias et al., 2004; Waehre et al., 2004). Furthermore, the clinical benefit of these drugs is manifested early in the course of lipid-lowering, before plaque regression could occur, and in angiographic studies it has been shown that reversal of arterial narrowing occurs slowly and only to a small extent (Rauch et al., 2000). Statins have been shown to be effective in primary stroke prevention in patients with proven coronary artery disease and in a recent study, high dose statins were proven effective for the secondary prevention of stroke (Amarenco et al., 2006). In observational studies it has also been noted that patients with rheumatoid arthritis who are taking TNF blockers such as infliximab have lower rates of cardiovascular disease (and of pro-inflammatory CD4⁺ CD28⁻ T cells); however, the toxicity of these agents precludes their use for vascular disease prevention at the present time.

Summary

The role of inflammation and the immune system in the evolution of ischemic brain lesions, stroke-related reperfusion injury and the development of atherosclerotic vascular disease has been increasingly appreciated since the late 1980s. However, the degree and mechanisms by which inflammation may impact on clinical and tissue outcome after stroke are still being debated. On one hand inflammation is believed to be harmful, by exacerbating ischemic brain injury in the early days after stroke, while, weeks to months after stroke, inflammatory cells may be beneficial through the promotion of tissue repair and remodeling. Brain-induced systemic inflammation may increase patients' susceptibility to infections after stroke. Specific components of the inflammatory process may be potential targets for pharmacological intervention for acute ischemic stroke as well as for the prevention of stroke and cerebrovascular disease. There appears to be an increasingly complex interplay between the immune system and the brain and the vasculature in stroke that could impact on the extent and severity of vascular disease and on stroke outcome and recurrence.

This highlights the rationale for using *newer technologies* for cellular and molecular profiling of blood, brain tissue and atherosclerotic plaques in clinical and translational research studies. This is now possible using multiple combinations of antibodies in flow cytometry studies and with microarray analyses. These studies may permit identification of functional classes of lymphocytes that impact on disease severity and outcome (cf, using flow cytometry, CD4⁺ CD28⁻CD161⁺

T cells contributing to coronary artery plaque destabilization in acute coronary syndromes, Nakajima et al., 2002), and may permit reclassification of disease (cf, using gene expression profiling, novel subgroups of B cell lymphoma in gene expression studies, Alizadeh et al., 2000). Panels of genes from profiling of peripheral blood mononuclear cells show vascular and inflammatory genes that support current concepts of the stroke-related inflammatory process, and may even eventually provide clues to a possible brain signaling mechanism to the circulating blood after stroke.

Many aspects of the role of inflammation and the immune system in stroke remain controversial (Chamorro and Hallenbeck, 2006). However, more refined characterization of immune responses after stroke may suggest new and different therapeutic targets for acute ischemic stroke, in addition to novel approaches that are ongoing for the prevention of cardiovascular disease.

Review Questions/Problems

1. Immune cells involved in the evolution of ischemic brain lesions include:

- a. Microglia
- b. Neutrophils
- c. Monocytes
- d. Lymphocytes
- e. All of the above

2. Immune cells involved in stroke-related inflammation stroke are predominantly derived from the circulating blood.

true/false

3. Leukocyte infiltration across the blood brain barrier after ischemic stroke is dependent on the expression of adhesion molecules on leukocytes and endothelial cells.

true/false

4. Molecular mediators of inflammation after ischemic stroke include

- a. cytokines
- b. chemokines
- c. complement
- d. a and b
- e. a, b and c

5. The first immune cell responders after ischemic stroke are the brain microglia.

true/false

6. The neurovascular unit is comprised of the following:

- a. astrocytes
- b. neurons
- c. smooth muscle cells
- d. endothelial cells
- e. all of the above

- 7. The effects of ischemic stroke on the systemic circulation include:**
- increased susceptibility to infection
 - sensitization of circulating lymphocytes to brain antigens
 - both a and b
 - neither a or b
- 8. Atherosclerosis is now regarded as a chronic inflammatory disorder as opposed to one of lipid storage.**
- true/false
- 9. Neutrophils are the major inflammatory cells contained within atherosclerotic plaques.**
- true/false
- 10. Features of the vulnerable plaque include:**
- more prone to rupture
 - heavy inflammatory cell infiltrate
 - thin fibrous cap
 - a, b and c
 - a and c
- 11. Discuss the role of the immune system before and after ischemic and hemorrhagic stroke.**
- 12. Discuss the potential of immunomodulatory approaches for stroke treatment and prevention.**

Neurogenesis and Brain Repair

G. Jean Harry

Keywords Doublecortin; Epidermal growth factor; Fibroblast growth factor; Nestin; Progenitor cells; Stem cells, Radial glia; Rostral migratory stream; Subventricular zone; Subgranular zone

32.1. Introduction

Neurogenesis is a critical process in the formation and development of the neurons that comprise the brain. More recently, the identification of neurogenic regions in the adult brain has suggested that the general process of neurogenesis assumes a role in maintaining the normal brain as well as contributing to the repair of the brain following injury. As identified, adult neurogenesis is the production of new neurons in the adult brain. This is a complex process that is initiated with the division of a precursor cell and, in some cases, neural stem cells that progresses to the generation of functional new neurons. The environments within these neurogenic regions provide intrinsic factors to stimulate and maintain this as a normal process. These include a number of the various growth factors. In addition, there are a number of extrinsic factors that can stimulate this process including life style and environment, as well as, factors that can inhibit the normal process, such as depression. The potential of these cells to assist in the repair of the brain following injury has fostered the generation of a significant body of research to determine the signals and factors that stimulate the generation and survival of newly generated cells. In addition, efforts to understand the various stimuli that can drive the progenitor or stem cell to a mature neuron or to an oligodendrocyte for the production of myelin have contributed a wealth of information on the nature and plasticity of these cells and this process. The current chapter will address the basic dynamics of neural development with regards to the generation, migration, and maturation of neurons as they provide information to understand the dynamics required for the adult neurogenesis. The identification and details of the neurogenic regions in the adult brain, the growth factors that contribute to maintaining these regions, and the response to injury will be discussed. It is the intent of this

chapter to serve as an introduction to adult neurogenesis that can be used as a base for further study and evaluation of the increasing amount of data that is currently being generated.

32.2. Neurogenesis and Classification of Cells

32.2.1. Neural Development

In the normal process of nervous system development, organogenesis occurs during the period from implantation through mid-gestation. Neurogenesis is a complex process involving proliferation, migration, differentiation, and survival. It is characterized by an expansion phase in which stem cells undergo massive symmetric divisions followed by periods where expanded precursor cells give rise to differentiating cells (Gotz and Huttner, 2005). The complex architecture of the brain requires that different cell types develop in a precise spatial relationship to one another. To accomplish this, neural stem cells and their derivative progenitor cells generate neurons as well as astrocytes and oligodendrocytes by asymmetric and symmetric divisions. Stem cells are characterized by their ability for self-renewal with cell division generating at least one identical copy of the mother cell. Symmetric division yields two identical copies and asymmetric division produces one new identical stem cell and one that is determined toward a certain cell lineage. It is these cells that are often referred to as progenitor cells given the reduction in stem cell properties. However, these progenitor cells can dramatically expand in number of new cells. In the development of the brain, such cells can undergo a terminal symmetrical division leading to two differentiating cells (Takahashi et al., 1996).

In some parts of the nervous system, particular kinds of cells are generated from committed progenitor or “blast” cells. These cells proliferate symmetrically and then differentiate. Examples of such progenitors are the sympathoadrenal progenitor and the O2A progenitor from the optic nerve. As initially described, glia O2A progenitor cells first give rise to oligodendrocytes around the time of birth and begin to generate type 2 astrocytes during

the second postnatal week (Raff et al., 1983). During this time, platelet-derived growth factor (PDGF) is an important mitogen for the O2A progenitor. The differentiation of type 2 astrocytes is timed by cell-extrinsic factors. For example, ciliary neurotrophic factor (CNTF) is a diffusible signal that, in association with other signals of the extracellular matrix, is required to induce O2A progenitors to develop into type 2 astrocytes. The current thought is that the NG2 cells of the brain may contain the O2A progenitor cells (Nishiyama et al., 1996; Dawson et al., 2000; see below for additional discussion).

In the formation of the cerebral hemispheres, neurogenesis begins during fetal development; gliogenesis produces astrocytes followed by development of oligodendrocytes. For each cell type, temporal differences in cell production are maintained. For example, the first-generated neurons reach their final position before subsequent generations of neurons. The migration of neuronal precursors plays a role in establishing the identity of some neurons and defining the functional properties and connections of the neuron (Sidman and Rakic, 1973). This translocation is achieved by a combination of the extension of cell process, attachment to the substratum, and subsequent pulling of the entire cell by means of contractile proteins associated with an intracellular network of microfilaments. Directional control occurs as cells move along "guide" cells or according to a concentration gradient of chemotropic molecules. Positional identity of precursor cells is also spatially and temporally regulated by transcription factor patterns.

The radial glial cell processes serve to guide neurons from the zone of neuronal generation to the zones for final settlement and the laminar features of the cortex are generated over time by differential movement of groups of neurons born at different times. These cells also divide asymmetrically to give rise to another radial glial cell while the second cell can differentiate into a neuron. Thus radial glial cells may represent a unique stem cell population (Gaiano et al., 2000; Malatesta et al., 2000). In addition to the radial glia having stem cell potential, astrocytes isolated from the embryonic and early postnatal CNS display stem cell functional features (Laywell et al., 2000). In examining various precursor cells in culture, specific culture conditions can induce some precursors to show a change in commitment such as, the oligodendrocyte precursor cells (Kondo and Raff, 2000a) and transit-activating precursors (Doetsch et al., 2002). These cells can be reprogrammed to multipotent stem cells by the action of cytokines and epidermal growth factor (EGF).

32.2.2. Neurogenic Potential in the Adult

Select areas of the brain contain populations of progenitor cells with various proliferative and migratory potentials (Altman, 1969; Kaplan and Hinds 1977; Altman and Bayer, 1990). In the adult mammalian brain, neurogenesis continues in restricted germinal regions: the subependymal zone of the lateral ventricle subventricular zone (SVZ) and the subgranular zone (SGZ) between the hilus and the granule cell layer of the hip-

pocampal dentate gyrus. Characterization of adult cells found in these proliferative domains demonstrated that the appropriate neurogenic signals are present and continuously support the stem/progenitor cell population. In addition, a third population of stem/progenitor cells may reside within the brain in the form of cells with astrocyte-like properties (Laywell et al., 2000; Magavi and Macklis, 2001).

Mitotically active precursor cells in the adult brain consist of a heterogeneous population of cells including stem cells with the capacity for continual self-renew and undergo multilineage differentiation in that they can differentiate into several distinct cell types (Alvarez-Buylla et al., 2001; Suslov et al., 2002). As compared to the multipotent stem cell, progenitor cells do not have the ability for continual self-renewal and have a limited multipotent capacity. The term "precursor cell" can refer to cells for which there remains limited proliferative ability but the differentiation fate is fairly determined. While a resident stem cell population has been demonstrated within the adult subependyma of the rostral lateral ventricle (Reynolds and Weiss, 1992; Morshead and van der Kooy, 2001; Gritti et al., 1996), such a prominent population has not been clearly demonstrated in the SGZ. Characterization of SGZ cells suggests that while some cells meet the criteria of stem cells, most studies characterizing proliferative SGZ cells suggest that they are primarily progenitor cells (Seaberg and van der Kooy, 2002; Bull and Bartlett, 2005).

The proliferative capacity of cells from these zones can be evaluated with the isolation of cells to form spherical, detached colonies called neurospheres (typically 50–140 μ m in diameter). The generation of a neurosphere is not conclusive evidence of stem cell presence as both stem cells and progenitor cells are capable of forming such spheres (Reynolds and Rietze, 2005). An additional step for evaluation requires a limiting dilution neurosphere assay in which cells are plated by serial dilutions and analyzed for size of neurospheres and frequency of colony-forming cells. This allows for determination of stem cell and progenitor cell contributions. Under these conditions, the largest colonies (>1.5 mm diameter) originate from stem cells while progenitor cells form small colonies (Reitze and Reynolds, 2006). Cultures of stem cells can be expanded continuously while those of progenitor cells gradually diminish. Other ways to distinguish between the two cell types is in their response to mitogens such as, fibroblast growth factor-2 (FGF-2) and EGF with progenitor cells showing a greater responsiveness to FGF-2. In addition to proliferation, growth factors and other signaling molecules are critical for the differentiation of these newly proliferated cells. Multipotency can be assessed with the removal of EGF and FGF-2 and the addition of other factors to the culture medium. Neurospheres containing stem cells are multipotent and can produce neurons, astrocytes, and oligodendrocytes. If the neurospheres are comprised of progenitor cells, differentiation will generate astrocytes and oligodendrocytes and differentiation to neurons and glia will occur with the addition of brain derived growth factor (BDNF).

FIGURE 32.1. Schematic diagram of a sagittal section of the mouse brain localizing neurogenic regions. (A) dentate granule cell layer of the hippocampus. Newly proliferating cells in the subgranular zone (SGZ) are represented as dark cells along the inner border of the blades of the dentate. (B) subventricular zone (SVZ). (C) Extension of the ventricular system and the presence of newly proliferating cells within the ventricle noted as dark cell. RMS—rostral migratory stream. OLB—olfactory bulb.

32.2.2.1. Subventricular Zone

Cells generated in the SVZ migrate tangentially through a network of interconnecting pathways distributed throughout the wall of the lateral ventricle. The heterogeneous neuroblasts originating in the adult SVZ migrate in a chain-like manner towards the olfactory bulb (OB) along a defined pathway called the rostral migratory stream (RMS) (Lois et al., 1996). These migrating neuroblasts (type A cells) show a spindle-shaped cell body with one or two cell processes. Their elongated nucleus displays a dispersed chromatin pattern with small aggregates of condensed chromatin masses, 2–3 small nucleoli, and possible nuclear indentations. They have scant and electron-dense cytoplasm with many ribosomes, a small Golgi apparatus, few cisterna of rough endoplasmic reticulum, and many microtubules distributed along the long cell axis. There are no dense bodies, lipid droplets, or microvilli. These cells are immunopositive for nestin, the polysialylated form of the neural cell adhesion molecule (PSA-NCAM), TuJ1 and are immunonegative for glial fibrillary acidic protein (GFAP) and vimentin (Doetsch et al., 1997). (The details of each marker will be discussed later). During their migration, in the absence of radial glia or axonal guidance, the cells maintain contact with each other to reach the OB and differentiate into granule and periglomerular neurons. Cell differentiation is influenced by the expression of specific transcription factors in the SVZ or during migration in the RMS. For example, the transcription factor Pax6 is required for the production of a specific subpopulation of OB neurons (Kohwi

et al., 2005). It promotes the generation of neuronal progenitors directing them towards the dopaminergic periglomerular phenotype that is predominantly generated in the RMS (Hack et al., 2005). The transcription factor, Olig2, opposes Pax6 and promotes oligodendrogenesis (Hack et al., 2005).

In the rodent, the primary target site for newborn cells from the SVZ is the OB; however, more recent studies suggest that other brain regions may also receive cells (Arvidsson et al., 2002). This would support a role for stem/progenitor cells characterized in the primate SVZ (Quinones-Hinojosa et al., 2006; Tonchev et al., 2006). Several lines of evidence suggest that the SVZ astrocyte serves as the primary precursor for these new neurons. Astrocytes in the SVZ, type B1 and B2, have distinct morphological characteristics (Doetsch et al., 1997) and express vimentin, nestin, and GFAP but not PSA-NCAM or TuJ1. Transiently amplifying progenitor cells (type C cells) are smooth and spherical, have large nuclei with deep indentations, dispersed chromatin pattern, and large reticulated nucleolus. The Golgi apparatus is large, there are fewer ribosomes than in the type A cells, and they lack intermediate filament bundles. Type C cells stain for nestin, are immunonegative for PSA-NCAM, TuJ1, GFAP, and vimentin. They express the epidermal growth factor (EGF) receptor, express the Dlx2 transcription factor, and are found in small clusters in the SVZ, as well as, isolated cells. NG2 cells in the SVZ display a transit-amplifier type C cell phenotype and may provide a significant proliferative progenitor pool in the brain (Aguirre et al., 2004) Figure 32.1.

32.2.2.2. Subgranular Zone

A relatively small number of proliferating cells derived from the cells of the hippocampal pseudostratified ventricular epithelium during embryonic stages continue to reside in the hippocampal hilus (Nowakowski and Rakic, 1981). In the rodent, this population is established at birth and during the early postnatal period. This intrahilar population produces about 80% of the cells of the dentate granule cell layer (Bayer and Altman, 1975). In humans and monkeys, this is reversed and only about 20% production occurs postnatally (Nowakowski and Rakic, 1981). This zone includes the basal cell band of the granule cell layer and a two-cell-wide layer into the hilus. Several types of neuronal and glial progenitor cells, as well as, astrocytes with radial glial elements, are within this neurogenic zone (Seri et al., 2004; Filippov et al., 2003). Similar to the SVZ, astrocyte-like B cells give rise to the transiently amplifying progenitor C cell to produce the migrating A cell. The putative stem cells morphologically resemble radial glia and have astrocytic properties. They have a large triangular-shaped soma with long apical processes reaching into the granule cell layer. Sparse branching occurs into the outer third of the granule cell band (Filippov et al., 2003). Radial glia-like cells expressing nestin, type-1 cells, consistently express the astrocytic protein, GFAP, and are negative for the astrocytic marker S100 β . Type-2 cells are nestin-expressing cells with irregularly shaped nucleus, dense chromatin, and short processes oriented parallel to the SGZ. These cells are either negative (type 2a) or positive (type 2b) for the immature neuronal marker doublecortin (DCX). Type 3 cells are DCX positive but nestin negative, with a rounded nucleus and express PSA-NCAM and Prox-1. The type-3 stage comprises a transition to a postmitotic immature neuron. Adult-generated hippocampal cells migrate primarily to the inner third of the granular cell layer (GL; Kempermann et al., 2004). The exit from the cell cycle into the terminal postmitotic differentiation of granule cells is accompanied by a transient expression of calretinin occurring with expression of Prox-1 and the postmitotic neuronal marker, NeuN. With maturation of the granule cells, calbindin, rather than calretinin, is expressed (Brandt et al., 2003). The immature granule cells have a globular cell body with many fine dendritic processes extending into the molecular layer (Kempermann et al., 2004) and axons into the CA3 pyramidal cell layer (Hastings and Gould, 1999). In the GL these cells assume the nuclear and cytoplasmic morphology of the surrounding neurons, express biochemical markers of immature and mature neurons, and receive functional GABAergic contacts. When the neurons are established in their final position within the GL, they develop spiny dendrites reaching the outer molecular layer and functional glutamatergic afferents increase. With the final stages of maturation, the cells obtain perisomatic GABAergic contacts. When these cells are selectively removed from the brain regions and cultured as neurospheres, they can differentiate into various cells and the neurons can form functional synapses (van Praag et al., 2002; Schmidt-Hieber et al., 2004).

32.3. Methods Used to Detect Newly Generated Cells

32.3.1. Markers Used for Cell Proliferation and Stem/Progenitor Cells

The incorporation of bromodeoxyuridine (BrdU) into replicating DNA during the S-phase of the cell cycle is a marker for DNA synthesis. BrdU incorporation can represent an increase in the number of proliferating cells or simply changes in cell cycle, active DNA repair (Selden et al., 1993), apoptosis (Katchanov et al., 2001), or development of tetraploidy (Yang et al., 2001); thus, in the absence of caution, false conclusions are possible regarding neurogenesis (Rakic, 2002). However, given the usually close link between BrdU incorporation and cell proliferation, it was initially used by Nowakowski et al. (1989) as a tool for studying cell proliferation in the developing nervous system. As an alternative, or complement, Ki-67 is a nuclear protein expressed at different levels in dividing cells for the duration of their mitotic process. There are however, questions with regard to whether the signal is sufficient to detect the early G1 phase of the cell cycle. While Ki-67 immunohistochemistry will provide a snapshot of a specific window in time, BrdU incorporation into cells can be followed over time. In the normal adult brain, the number of cells in the SGL that incorporate BrdU or immunostain for Ki-67 is histologically represented by a sparse number of positive cells along the inner blade of the dentate (Kee et al., 2002). Despite the technical problems with BrdU, results indicating significant amounts of adult-generated cells in the hippocampus (Cameron and McKay, 2001) are supported by labeling of newly generated cells with retroviral vectors and integration into the host genome (Lewis and Emlen, 1994). Co-immunostaining of the cells with neuronal specific markers suggests that these cells can differentiate into neurons. However, most of the newborn cells undergo cell death during the first several weeks after final cell division (Biebl et al., 2000; Dayer et al., 2003).

Additional methods of detection and tracking the fate of newly generated cells have been developed. Fluorescent markers have been combined with retroviruses for birth dating and tracking of cells (van Praag et al., 2002). Continued development of retroviral vectors has resulted in vectors to express transgenes, short-hairpin RNAs, and site-specific recombinase. Transgenic mice have been developed containing a restricted expression of a fluorescent marker in progenitor cells. For example, green fluorescent protein (GFP) under the regulatory control of the nestin gene produces animals with labeled progenitor cells and immature neurons in the dentate gyrus (Yamaguchi et al., 2000; Filippov et al., 2003). Under transcriptional control of proopiomelanocortin (POMC) genomic sequences, cryptic sequences in the transgene provides expression in immature dentate granule cells that are approximately 2 weeks postmitotic (Overstreet et al., 2004). Alternatively, one can examine the progenitor cell popula-

tion based on their distinct membrane properties. Newborn cells display high input resistance (Ambrogini et al., 2004; Schmidt-Hieber et al., 2004) and a lower threshold for activity-dependent synaptic plasticity such as long-term potentiation is seen in immature granule neurons (van Praag et al., 1999; Schmidt-Hieber et al., 2004).

32.3.2. Neural Cell-Specific Markers

Neuronal Nuclei (NeuN) expression is restricted to postmitotic neurons. The protein is localized in the nucleus with staining occurring in the cytoplasm near the nucleus and in some cases extending into the neurites. NeuN can bind to DNA and may serve as a transcription factor that can be induced with the initiation of terminal differentiation (Sarnat et al., 1998). There is no reported case of NeuN expression in glial cells. NeuN immunoreactivity can be diminished in pathological conditions; however, loss of staining does not necessarily equate to loss of neurons nor does a reemergence of staining indicate neurogenesis (Unal-Cevik et al., 2004).

TuJ1 is the clonal designation for an antibody used against β -III-tubulin, a minor neural isotype of tubulin associated with neurons. Immature neurons in the neurogenic zones express β -III-tubulin; however, there is little data regarding the re-expression in mature neurons and there is some data suggesting a limited overlap with non-neuronal lineages. TUC4 (TOAD-64, Ulip-1, DRP-3, CRMP4) is expressed by postmitotic neurons at the stage of initial differentiation with the highest expression occurring in the growth cone. The duration of the expression after cells have become postmitotic is not known. With additional markers, it may offer information on the development of neurons either in the mature brain or following injury. It does not offer information on the net level of neurogenesis.

In neurogenic regions, PSA-NCAM is a specific marker for the neuronal lineage. The polysialic acid residue reduces the cell adhesion of NCAM; thus, it is found on migratory neuronal cells and identifies type-2b and type-3 cells in the dentate gyrus and C-cells in the SVZ and RMS (Seki, 2002). Expression of PSA-NCAM is thought to occur during post-neuronal differentiation and while, associated with neurogenesis, it is also associated with synaptic plasticity and can be expressed on glial cells in non-neurogenic brain regions (Kiss et al., 1993). In the neurogenic zones, the temporal expression of PSA-NCAM parallels that of doublecortin but offers information of the dendritic arborization of the cells.

Doublecortin (DCX) is a microtubule-associated protein expressed in neuronal cells during migration. It has both cytoplasmic and nuclear localization and is enriched in the leading processes of these cells (Schaar et al., 2004) and in the growth cones of neurites. DCX is transiently expressed during adult neurogenesis and identifies the phase of migration and neurite extension of type-2b and type-3 cells (Brandt et al., 2003; Brown et al., 2003a; Ambrogini et al., 2004). The expression persists into the postmitotic stage of neurons when it overlaps

with calretinin expression (Brandt et al., 2003). Throughout the brain, DCX expression overlaps with PSA-NCAM with some evidence of staining of NG2 glial cells.

Nestin is an intermediate filament protein that is localized to a subpopulation of precursor cells in both the SGZ and the SVZ (Filippov et al., 2003). It is expressed at low levels in the neurogenic regions and in blood vessels. In green fluorescent protein (GFP)-nestin transgenic reporter mice, positive cells overlapping with DCX can be found through the entire brain. With injury, both nestin and DCX positive cells are found at the target site and can occur in the absence of neurogenesis. This reflects the residual capability of cells within the non-neurogenic region as induced with changes in the microenvironment or rather, a limited specificity of these markers.

The chondroitin-sulfate proteoglycan, NG2, is a transmembrane protein containing extracellular laminin-like domains. Cells expressing NG2 are a prominent progenitor population in the postnatal brain (Dawson et al., 2000). These cells can be either highly proliferative and migratory or slowly dividing and non-migratory (Belachew et al., 2003; Aguirre et al., 2004). It is thought that NG2 labels primarily precursor cells in the oligodendrocytic lineage and secondarily, a specific type of astrocyte that is closely associated with synapses and axonal structures. The sensitivity of NG2 as a marker for neurogenesis is not clearly defined but may indicate the involvement of radial glia as a precursor cell.

32.4. Regulatory Factors Influencing Adult Neurogenesis

As in many other forms of repair mechanisms for the nervous system, such as neurite outgrowth, reactive synaptogenesis, and remyelination, it is thought that the mechanisms involved recapitulate those that occur in normal development. This assumption has more recently been applied to the mechanisms operating to control stem cell proliferation (Vaccarino et al., 2001). During development of the brain, neural stem cells follow an orderly sequence of events resulting in the coordination of multiple signals to produce specific products at specific critical times. In the adult, this may not be the case, but rather that the system responds to local environmental influences to produce a response appropriate for the situation. Questions that continue to be raised are: What intrinsic properties render a progenitor cell proliferative and migratory? What signaling molecules promote proliferation and migration in quiescent neural progenitors? To gain a better understanding of the plasticity of this process, changes in the number of BrdU+ or viral+ cells within the brain have been examined under various conditions. This process is regulated by a wide range of molecules such as hormones, neurotransmitters, growth factors, and transcription factors. It is also regulated by aging, nutrition, physical exercise, and environmental enrichment. Additional details for some of these modulatory factors will be discussed in the following sections.

32.4.1. Age

While the proliferative activity within the brain germinal zones declines with increasing age, cell proliferation continues throughout life (Altman and Das, 1965; Kuhn et al., 1996; Seki, 2002; Hallbergson et al., 2003; Duman, 2004; Maslov et al., 2004). An age related decrease in hippocampal neurogenesis (Kuhn et al., 1996; Lichtenwalner et al., 2001; Jin et al., 2003; Heine et al., 2004) has been linked to the decline in cognitive function with aging. With a decrease in the generation of new neurons as a function of age, the response to either the environment or injury may override any such changes. For example, an enriched environment initiated in the later half of life significantly increased the level of adult hippocampal neurogenesis in 20-month-old rodents (Kempermann et al., 2002). With transient forebrain ischemia, 2-year-old rats show a greater increase in BrdU incorporation into cells in the SGZ as compared to young adults. However, fewer of these cells survive and proportionally fewer differentiate into mature neurons (Yagita et al., 2001). These age-related changes in neurogenesis may reflect the influences of changes in the host environment with regards to mitogenic and differentiation factors. With increasing age, the ratio of glial cells to neurons increases, often resulting in glial hypertrophy (Cotrina and Nedergaard, 2002). With aging, the increase in glucocorticoids has been associated to synaptic loss and inhibited production of new granule neurons (Nichols et al., 2005). The decreased neurogenesis in the aged brain may be related to a decrease in insulin like growth factor-1 (IGF-1) (Aberg et al., 2000; Lichtenwalner et al., 2001) or increased oxidative stress (Nicolle et al., 2001).

To address such questions of the environment, experimental models of fetal cell transplants into the brain have been employed. Quite often, a decrease in cell survival is seen with increasing age of the host. The survival rate can be improved if the fetal cells are incubated with various signaling factors (e.g., BDNF, NT-3, and caspase inhibitors) prior to transplantation. Using the olfactory bulb as an example, in a developing system, interneurons produced in the SVZ and partly in the RMS (Pencea and Luskin, 2003) populate a newly developing structure; while in the adult, the interneurons are integrated into an existing OB circuit. The origin, final target site, and distribution profiles are age dependent. Newly generated cells are evenly distributed across the anteroposterior axis of the OB and the relative contribution of SVZ versus localized bulbar neurogenesis increases from the neonate to the young adult. Cells derived from the SVZ/RMS in the neonate are targeted to the superficial regions of the GL and in the young adult, they are found primarily in the deeper regions (Lemasson et al., 2005). The fact that newborn cells reach the OB target faster when generated in the young adults as compared to the neonates (Lemasson et al., 2005) suggests the need for maturation of specific processes and anatomical structures to allow for rapid migration of cells.

32.4.2. Life-Style

Conditions normally associated with a decrease in neural activity such as depression or those associated with stress can result

in a decrease in an already minimal process (Duman, 2004). In experimental models of stress, cell proliferation within the SVZ and SGZ is decreased and this decrease is often associated with a decrease in memory performance. Pharmacological antidepressant agents such as lithium can enhance hippocampal neurogenesis (Chen et al., 2000). A chronic increase in the levels of corticosteroids has been proposed as one primary mediator of age-related decline in neurogenesis; however, such decline is not necessarily associated with an increase in circulating hormone levels (Heine et al., 2004). Yet, with age, the expression of corticosteroid receptors shifts to a more immature state possibly representing a shift in receptor sensitivity.

Additional life-style modulators have been examined for their stimulatory role in adult neurogenesis. Rodents maintained on dietary restriction show an increase in hippocampal neurogenesis, perform better on learning and memory tasks, show increased resistance to neuronal degeneration, and have increased BDNF levels in the hippocampal and cerebral cortex (Lee et al., 2000, 2002; Duan et al., 2001). Initial studies suggested that neurogenesis might be activity dependent and regulated related to normal behavior (Kempermann et al., 1997). The rate of neurogenesis in animals increases following voluntary exercise, housing in an enriched environment, and with exposure to specific learning and performance paradigms (Gould et al., 1999; Nilsson et al., 1999; van Praag et al., 1999). Environmental enrichment increases neurogenesis in the DG but not the SVZ and is mediated partly by BDNF (Brown et al., 2003b). Such increases can occur with a concurrent improvement on learning tasks dependent upon the hippocampus and inhibition of neurogenesis decreases learning performance. The impact of environmental enrichment is decreased when the basal level of neurogenesis is increased by other factors such as social dominance (Kozorovitskiy and Gould, 2004). These studies suggest that while a number of environmental factors can increase neurogenesis in the normal brain, there are limits to this induction.

32.4.3. Endogenous Factors

Signals in the cell environment regulate the maintenance, proliferation, and neuronal fate commitment of the local stem cell populations (Alvarez-Buylla and Lim, 2004; Gotz and Huttner, 2005). *In vitro* and *in vivo*, numerous factors have been shown to support the production of neural cells from the SVZ and SGZ. Factors derived from cells surrounding the neural stem cells participate in the regulation of neurogenesis such as, growth factors and other small molecules including, FGF2, PACAP, IGF-1, NT3 (Vaccarino et al., 2001, review). As one would expect, the number of factors identified continues to increase with additional work and spans many of the same factors identified as critical for organogenesis and the initial neurogenesis during development.

32.4.3.1. Sex Hormones

The primary support for a hormonal influence in adult neurogenesis comes from the reports of neural progenitor cell

proliferation being higher in the female rodent as compared with the male (Tanapat et al., 1999; Abrous et al., 2005). In the female rodent, cell proliferation peaks in proestrous with the increase in estrogen and decreases in phases of low estrogen (Tanapat et al., 1999). This level of proliferation is higher than what is seen in males (Abrous et al., 2005). The effects of estradiol are mixed with the induction of embryonic precursor cell proliferation (Brannvall et al., 2002; Ormerod et al., 2003) yet, a reduction in the mitogenic effects of EGF in rat neural precursor cells. The neuroactive progesterone metabolite, allopregnanolone (3 α -hydroxy-5 α -pregnan-20-one) induces a significant increase in the proliferation of neuroprogenitor cells derived from the rat hippocampus as well as, cortical derived human neural stem cells (Wang et al., 2005).

32.4.3.2. *Growth and Neurotrophic Factors*

As extracellular signaling molecules, growth factors have diverse effects on neurogenesis, proliferation, and maintenance of new neurons. Cell surface adhesion and recognition molecules mediate interactions between individual cells and between cells and the extracellular matrix. Additional interactions occur by means of diffusible molecules such as, growth factors and trophic agents. Studies on neural development have identified several trophic factors important for neuronal survival and growth that appear to also contribute to the generation of new cells in the adult brain. Brain-derived neurotrophic factor (BDNF), IGF-1, erythropoietin, epidermal growth factor (EGF), and the basic fibroblast growth factor (FGF2) (bFGF) have been shown to support neural cell production.

EGF is known to be important in the proliferation and maintenance of embryonic and adult neural stem cells (Doetsch et al., 1999, 2002) and EGFR is involved in the radial migration and maturation of neural precursors during embryonic cortical development (Caric et al., 2001). EGF has a strong mitogenic effect on stem cells in culture and upon withdrawal the cells can be induced to differentiate. With the direct infusion of EGF into lateral ventricles proliferation increases within the SVZ (Kuhn et al., 1997) and neurogenesis following ischemia can be augmented (Nakatomi et al., 2002). Both the basic and acidic forms of fibroblast growth factor (FGF) stimulate outgrowth of neurites, reduce the effects of injury, and enhance regeneration. FGF-2 plays a critical role in signaling for hippocampal neurogenesis in normal rodents (Cheng et al., 2002), aged mice (Jin et al., 2003), and following traumatic brain injury (Yoshimura et al., 2001). Following infusion into the ventricle, FGF-2 expands dividing cells of the SVZ and induces net neurogenesis in the OB (Kuhn et al., 1997). FGF-2 protein is up regulated within the hippocampus with seizures induced by kainic acid and after focal cerebral ischemia. With both models of injury, the induction of neurogenesis is significantly decreased in FGF-2 null mice suggesting a regulatory role for this growth factor (Yoshimura et al., 2001).

Nerve growth factor (NGF) is required for survival and neurite outgrowth of cholinergic neurons of the basal forebrain,

sympathetic postganglionic neurons, and sensory ganglion cells derived from the neural crest. In the developing and regenerating peripheral nerve, it is produced by both Schwann cells and macrophages. The highest level of NGF occurs in the hippocampus and the cerebral cortex, both of which are targets for cholinergic magnocellular neurons of the basal forebrain. A member of the same family, brain-derived neurotrophic factor (BDNF) is a 12.3 kDa basic protein and, as a growth factor, it has its maximum effect during the time when embryonic neurons contact targets in the CNS. BDNF contributes to brain synaptic plasticity, influences aging, and promotes neurogenesis and cell survival (Mattson et al., 2004). This growth factor assists in maintaining the basal activity in the proliferative zones of the brain (Lee et al., 2002), can directly stimulate neurogenesis (Scharfman et al., 2005), and with voluntary exercise or enriched environment, is upregulated in the dentate gyrus (Farmer et al., 2004). It has also been reported to mediate the effects of antidepressant drugs on hippocampal neurogenesis (Sairanen et al., 2005). However, over expression of BDNF in the hippocampus decreases the neurogenic response to ischemic insult (Larsson et al., 2002) and the blockage of endogenous BDNF increases ischemia induced hippocampal neurogenesis (Gustafsson et al., 2003). The inhibitory effects may be associated with the induction of progenitor cells rather than stem cells in the SGZ and the dysregulatory effects of chronic BDNF exposure as proposed by Larsson et al. (2002). This idea is supported by the work of Cheng et al. (2003) in which BDNF was found to reduce neuroprogenitor cell proliferation and enhance neuronal differentiation. Thus, in an ischemic injury, excess BDNF could serve to regulate neural progenitor cells in the SGZ with a down-regulation of excess proliferation and an induction of differentiation of the cells to the neuronal lineage. With a chronic BDNF administration, the regulatory balance would be disrupted resulting in a decrease in the overall neurogenic response.

The increased number of newly generated cells in the SGZ following life-style modulators, is thought to be due to the increase in cell survival and has been linked to increased protein levels for both BDNF and neurotrophin 3 (NT-3) (Lee et al., 2000, 2002; Duan et al., 2001). Ciliary neurotrophic factor (CNTF) is an acidic protein involved in type-2 astrocyte differentiation. Injection of CNTF into the mouse brain stimulates precursor cell proliferation with the CNTF receptor alpha expressed on GFAP-positive cells of the SVZ (Emsley and Hagg, 2003).

Insulin-like growth factor-1 (IGF-1) mediates BDNF action and, when administered either peripherally or directly into the ventricle, induces both cell proliferation and net neurogenesis (Aberg et al., 2000; Lichtenwalner et al., 2001). It is expressed in neurons with physical activity and many of the protective effects of exercise can be inhibited by blocking the uptake of either IGF-1 (Carro et al., 2001) or vascular endothelial growth factor (Trejo et al., 2001). IGF-1 can also inhibit some of the age-related decline in hippocampal neurogenesis (Lichtenwalner et al., 2001).

32.4.3.3. *Cell Adhesion Molecules*

Migration is influenced by the adhesion properties of the cells and the direct interactions between a cell and the extracellular matrix. These include cell adhesion molecules (CAMs), intercellular adhesion molecules (I-CAMs), integrins, and cadherins. CAMs are a family of high molecular weight cell surface glycoproteins with regulatory properties during neural development. Family members include neural CAM (N-CAM), neuronal-glia CAM (Ng-CAM-NILE or L1), tenascin, and adhesion molecule on glia (AMOG/beta2 isoform of the membrane Na, K-ATPase pump). N-CAM is widespread early in embryogenesis and in both neurons and glia throughout nervous system development. It mediates Ca²⁺-independent homophilic binding and aggregation of neuronal cells. N-cadherin is important in Ca²⁺-dependent cell-cell interactions. Tenascin is a large extracellular matrix glycoprotein implicated in cell proliferation and neural cell attachment. With the decline of tenascin expression begins the expression of L1, a protein involved in heterotypic binding between neuronal and neuroglial cells. Integrins are membrane receptors with ligands consisting of I-CAMs and other matrix components such as collagen, laminin, and fibronectin. Integrin activation can lead to rapid changes in cell adhesion properties in the local environment and can signal intercellular events. These receptors provide the developing neural cells a system for linking adhesion/migration information with other developmental signals controlling proliferation and differentiation. The tangential migration of neuroblasts is influenced by multiple molecular signals. The polysialylated form of the neural cell-adhesion molecule confers a migratory phenotype to neuroblasts (Pencea and Luskin, 2003). Directional migration is mediated by deleted in colorectal carcinoma and integrins (Murase and Horwitz, 2002). The soluble ligands Slit1 and Slit2 serve as guidance signals (Bagri et al., 2002).

32.4.3.4. *Other Developmental Signaling Factors*

Members of the receptor tyrosine kinase (RTK) family serve as signaling molecules. This large family includes the Eph family and their transmembrane-associated ephrin ligands and members of the Erb RTK family. They serve to influence the proliferation of cells in the SVZ (Conover et al., 2000). The RTK ErbB4 is expressed by neuroblasts located in both the SVZ and within the RMS (Anton et al., 2004). This kinase can be activated by multiple EGF-like domain-containing ligands including the neuregulins (NRGs). The NRGs induce the transcription of genes encoding acetylcholine receptor subunits and affect neuronal migration on radial glial guides in the cerebellum and the cerebral cortex through ErbB4 and ErbB2 receptors (Schmid et al., 2003). It has been proposed that ErbB4 activation helps to regulate the migration of precursors within the RMS and influence placement and differentiation into distinct interneuronal subsets. The Erb RTK family includes the epidermal growth factor receptor (EGFR) ErbB1 and its ligand EGF. EGF is known to be important in the proliferation and

maintenance of embryonic and adult neural stem cells (Doetsch et al., 1999, 2002; Yarden and Sliwkowski, 2001) and EGFR is involved in the radial migration and maturation of neural precursors during embryonic cortical development (Burrows et al., 1997; Caric et al., 2001; Ciccolini et al., 2005).

Wnt (Wingless) is important for self-renewal in hematopoietic stem cells. In the brain, it is important for induction of neural specification (Munoz-Sanjuan and Brivanlou, 2002). Wnt signaling increased the intracellular concentration of β -catenin which associates with transcription factors TCF/Lef for gene transcription. Adult hippocampal progenitor cells express receptors as well as other components of the Wnt/Beta-catenin signaling pathway (Lie et al., 2005). Wnt3a signaling is required for normal expansion of precursor cells in hippocampal development (Roelink, 2000). Wnt3 stimulates this signaling pathway primarily by astrocytes located in close proximity to neurogenic regions of the brain. The Wnt signaling may serve as a regulatory pathway in adult hippocampal neurogenesis and contribute to the determination of neuronal fate commitment, as well as, cell proliferation.

Sonic hedgehog (Shh) is critical for development and the patterning of the ventral brain (McMahon et al., 2003). It is required for progenitor cell maintenance (Machold et al., 2003). Secretion of the Shh protein increases cell proliferation in the SVZ and SGZ and is required for normal proliferation in the SVZ (Lai et al., 2003). Shh receptors, patched and smoothed, are expressed in the SGZ, as well as, in the hippocampus (Traiffort et al., 1999; Lai et al., 2003).

During development bone morphogenetic proteins (BMPs) activity induced proliferation via activation of the BMP-1A receptor however, the BMP-1B receptor up-regulates p21^{kip1} to inhibit the cell cycle (Panchision et al., 2001) thus, suggesting multiple functions. They can be potent inhibitors of SVZ neurogenesis and are produced by SVZ astrocytes (Lim et al., 2000). BMP2 can promote telencephalic neuroepithelial cells to differentiate as astrocytes. In the presence of leukemia inhibitory factor (LIF), a synergistic action is provided. The antagonist Noggin is secreted by ependymal cells and functions to promote neurogenesis by preventing BMPs from activating their receptors. This would then block the glial promoting effects of BMPs (Lim et al., 2000). The close interactions between the SVZ astrocytes and the ependymal layer maintain the necessary regulatory control or induction of SVZ neurogenesis.

Proneural basic-helix-loop-helix (HLH) transcription factors drive neurogenesis via cell-cycle exit specific protein expression (Guillemot, 1999; Kintner, 2002). The Sox B1 subfamily of the HMG-box transcription factors, (Sox 1–3) is expressed by precursors in the embryonic nervous system. They are expressed by most progenitor cells of the developing CNS. They are downregulated when the cells exit the cell-cycle and differentiate (Uwanogho et al., 1995; Pevny et al., 1998). It is thought that these factors maintain neural progenitors in an undifferentiated state thus, inhibiting neuronal differentiation. Sox2 is expressed in the germinative zones in the adult rodent brain while Sox3 is expressed transiently

by neural progenitors in the SVZ and dentate gyrus (Wang et al., 2006). In human embryonic stem cells, Sox3 is transiently induced with differentiation to neural progenitors, suggesting a role for neural stem cell maintenance. Some bHLH genes are involved in neural determination, others such as *Mash1* and *NeuroD*, are involved in terminal neuronal differentiation. The Proneural protein, Mash1 (mammalian achaete-scute homologue), is essential to the production of neurons in the embryonic ventral telencephalon (Casarosa et al., 1999). With other neurogenin family proteins, Mash1 promotes commitment of multipotent progenitors to neurons and inhibits astrocyte differentiation (Nieto et al., 2001). It is expressed and required for the generation of precursors in the SVZ of the postnatal brain for both oligodendrocytes and olfactory interneurons (Parras et al., 2004). Data is also available to suggest that a similar regulatory pathway involving activity of Mash1/Olig2 and *Dlx* is involved in the differentiation of both GABAergic interneurons and oligodendrocytes (Fode et al., 2000; Yun et al., 2002; Marshall et al., 2003).

Notch1 activation serves to prevent neuronal differentiation by maintaining cells in a precursor cell state (Chojnacki et al., 2003). Notch receptor signaling restricts the neurogenic potential of precursor cells by activating transcriptional repressors of the *Hes* gene family. These in turn suppress the expression of proneural bHLH proteins that can lead to the development of astrocytes (Tanigaki et al., 2001). A transient over expression of Notch1 in neural crest stem cells switches the cell lineage to glia from neuronal (Morrison et al., 2000).

The transcription factor cAMP response element-binding protein (CREB) is considered to be involved in the regulation of specific phases of adult neurogenesis in the SVZ/olfactory bulb system (Giachino et al., 2005) and in the SGZ for hippocampal neurons (Bender et al., 2001; Nakagawa et al., 2002).

32.5. Contribution of Glial Cells

The stimuli regulating adult neurogenesis also seem to affect gliogenesis. Several studies have demonstrated that cells expressing glial fibrillary acidic protein (GFAP) give rise to neurons in the adult dentate gyrus. Radial glial cells have a bipolar morphology with the cell soma residing in the ventricular zone or SVZ extending long basal processes to the pial surface and a short apical process in contact with the ventricular wall (Levitt and Rakic, 1980; Bentivoglio and Mazzarello, 1999). Notch1 signaling can promote radial glia differentiation (Gaiano et al., 2000). *In vivo* studies suggest that radial glial cells can serve as a source of neuronal precursor cells (Hartfuss et al., 2001; Noctor et al., 2002; Gotz et al., 2002; Ever and Gaiano, 2005). This has led to the concept that radial glia can serve as a source of new neurons (Alvarez-Buylla et al., 2001; Gregg et al., 2002). However, not all radial glial cells are actively dividing during neurogenesis and not all are neuronal precursors (Schmechel and Rakic, 1979; Gaiano et al., 2000). An additional potential source for radial glia lies in

the astrocytes population that has recently been shown to de-differentiate to immature radial glia as a function of cold temperature (Yu et al., 2006). Whether it represents an additional source of new neurons has not been determined.

In vivo, the contribution of GFAP expressing cells to neurogenesis appears to be from a sub-set of cells co-expressing both GFAP and nestin (Filippov et al., 2003), suggesting both a heterogeneity among the GFAP-expressing cells and a contribution to the generation of new neurons. In culture, GFAP-containing cells can show multipotency (Laywell et al., 2000;) while, other studies suggest that any such progenitor cells in the hippocampus require the actual presence of astrocytes to develop into neurons (Song et al., 2002). Kondo and Raff (2000a) showed that oligodendroglia progenitor cells cultured under specific conditions could be reprogrammed to multipotential neural stem cells able to generate both neurons and glia. Their further work proposed a critical role for Mash1 in the timing of oligodendrocyte development (Kondo and Raff 2000b); however, the work of Wang et al. (2001) did not support such a role for Mash1 but rather suggested a critical role for Id2 (inhibitor of DNA binding).

Cell-cell interactions between the newly generated neurons and non-neuronal cells have more recently been explored. Factors derived from local astrocytes participate in the regulation of proliferation and neuronal differentiation (Song et al., 2002). FGF-2 and CNTF are expressed by hypertrophic astrocytes in the denervated outer molecular layer of the hippocampus following lesion (Frautschy et al., 1991; Lee et al., 1997). FGF-2 protein is up-regulated within the hippocampus with seizures induced by kainic acid and after focal cerebral ischemia. With both modes of injury, the induction of neurogenesis was significantly decreased in FGF-2 null mice suggesting a regulation role for this growth factor in adult injury-induced neurogenesis (Yoshimura et al., 2001).

Cells immortalized from early postnatal neural precursors will readily migrate toward glioblastomas (Aboody et al., 2000). In glioblastoma-bearing mice, inoculation of such cells increased survival of the mouse with a greater survival seen if these cells were modified to over express interleukin-4 (Benedetti et al., 2000; Noble, 2000). Increased survival was seen with *in vitro* expanded neural precursor cell lines administered into gliomas (Staflin et al., 2004) and endogenous neural precursor cells show a strong tropism for glioblastomas (Glass et al., 2005). In mice, this attraction of precursors to glioblastomas declines with increasing age (Glass et al., 2005).

In the RMS, neuroblasts migrate tangentially in chains enwrapped by an astrocyte-derived tunnel-like structure termed the glial tube. This migration begins at birth yet, the astrocytes display a relatively homogeneous network and the glial tube does not become obvious until the third postnatal week of life (Peretto et al., 1997, 1999). The formation of the glial tube and the associated release of molecules to promote and accelerate neuroblast migration and the developmentally regulated expression of some integrins (Murase and Horwitz, 2002) may contribute to a more rapid and efficient cell turn-

over in the adult animal. In the olfactory epithelium, both stimulatory and inhibitory factors influence cell proliferation. *In vitro*, stimulatory factors include the fibroblast growth factors (FGFs), which increase the number of cell divisions that INPs undergo thus generating more neurons. FGFs also support the proliferation and survival of rare progenitors. *In vivo*, FGF8 is considered to be a good candidate for a positive FGF regulator. *In vitro*, other molecules have been reported to stimulate proliferation of OE cells and include: epidermal growth factor (EGF), TGF- β 2, TGF- α , and olfactory marker protein (OMP). The anti-neurogenic negative regulators include the bone morphogenetic protein (BMP) family possibly targeting the transcription factor Mash1 (Shou et al., 1999).

32.6. Models of Brain Injury Showing Induction of Neurogenesis

Post-development neurogenesis can be upregulated in response to a variety of stimuli including ischemia, seizures, and head trauma (Kempermann et al., 1997; Magavi and Macklis, 2001; Arvidsson et al., 2002; Nakatomi et al., 2002; Parent and Lowenstein, 2002; Parent et al., 2002; Kokaia and Lindvall, 2003).

32.6.1. Olfactory System Damage

In the olfactory epithelium (OE), undifferentiated progenitor cells generate new neurons throughout life. It has been a source of information regarding cell interactions and the molecular response of progenitor cells (Calof et al., 1996). OE neuronal progenitors lie in close proximity to the olfactory response neurons (ORNs); while, the SVZ as the origin of progenitors for the ongoing production of OB interneurons lies at a distance. Proliferating cells are located throughout the RMS and may respond differently to injury signals depending upon their placement within the migratory process. Physically, one can sever axons of the olfactory receptor neurons, remove the target site with an olfactory bulbectomy, or disrupt sensory input to the olfactory receptor neurons by a naris occlusion to block the nasal opening. Damage can also be induced with inhalation or direct application via nasal irrigation of chemical agents or exposure to corrosive gases.

The extent of recovery of the OB is dependent upon the extent to which ORNs are able to regenerate and re-innervate the tissue. Regeneration is more robust following nasal irrigation with either Triton X-100 or methylbromide as compared to the delayed progression of repair following zinc sulfate. Contact deprivation of olfactory receptor neurons with their target cells by axonal severing or olfactory bulb removal results in rapid apoptosis of mature ORNs followed by degeneration of the olfactory epithelium, and a permanent upregulation in proliferation of cells in the basal compartment of the epithelium for replacement. In the absence of an olfactory bulb with a bulbectomy, these cells turn over with a lifespan of 2 weeks, suggesting that functional connections with the

bulb is required for ORN maturation and survival. The high turnover of neurons provides for continued apoptosis in the region and suggests the ORN death may be involved in regulating proliferation of progenitor cells.

Naris occlusion usually involves the closure of one nostril during the early neonatal period and results in decreased sensory input to the ORNs, decreased volume of the ipsilateral olfactory bulb, and decreased proliferation of progenitor cells in the basal OE. When a reversible model is employed, the OE can rapidly recover from these changes with an increase in the number of newly generated neurons in the periglomerular layer, the target of afferent inputs from ORNs (Cummings and Brunjes, 1997).

32.6.2. Seizure-Induced Neurogenesis

Severe and sustained seizures lead to neuronal degeneration in the hippocampus via both a necrotic and apoptotic process. Single or intermittent seizures may or may not lead to neuronal damage. However, the assessment of damage becomes complex given the neurogenic capability of the hippocampus and the current evidence indicating that seizure activity alone will stimulate neurogenesis (Smith et al., 2005). Thus, the number of neurons within the dentate gyrus following insult will depend upon both cell death and cell replacement. It is thought that seizure-induced neurogenesis produces a surplus of granule cell neurons resulting in the formation of abnormal and aberrant neuronal circuits. In rodent models of temporal lobe epilepsy, seizures are associated with an increase rate of neurogenesis in the dentate gyrus within the first week (Bengzon et al., 1997; Gray and Sundstrom, 1998; Parent and Lowenstein, 2002). This induction occurs with a single short seizure period, a prolonged seizure activity, or with repeated kindled seizures induced by direct stimulation of by pilocarpine or kainic acid. Extended seizure activity induced by pilocarpine produces an increase in cell proliferation in the rostral forebrain SVZ with a large proportion of the cells differentiating into neurons. It also produces an induction in the caudal portion of the SVZ but a large proportion of these cells differentiate into glia. Induction in the SGZ also occurs with limbic kindling and intermittent perforant path stimulation. In the rat, both single and intermittent hippocampal kindling stimulations produce a marked increase in apoptosis in neurons along the hilar border of the granule cell layer within 5h of cessation of stimulation. This is accompanied by an increase in BrdU/NeuN+ cells (Bengzon et al., 1997) and an increase in BDNF protein levels.

32.6.3. Ischemia

Ischemic brain injury results in the death of distinct susceptible populations of neurons in the brain. In addition, the injury concurrently triggers cellular repair mechanisms. SVZ precursors can be recruited following transient middle cerebral artery occlusion (Jin et al., 2001; Zhang et al., 2001). In this stroke

model, extensive damage occurs to the striatum and the overlying parietal cortex. The new neurons migrate into the damaged striatum and begin to express striatal specific markers (Arvidsson et al., 2002; Jin et al., 2003; Parent et al., 2002). However, the functional significance of these new neurons remains in question, as the majority die within the first few weeks (Arvidsson et al., 2002). In addition, acute ischemic stroke increases proliferation in the SGL and migration to the hippocampal granule cell layer within 7–10 days post injury (Jin et al., 2001). Treatment with BDNF enhances the repair process and additional neurons are seen to replace pyramidal cells in the damaged CA1 hippocampal region (Nakatomi et al., 2002). While the CA1 region is known to be vulnerable to ischemic injury, cells along the inner blade of the dentate gyrus at the SGL show signs of injury and express active caspase-3, indicative of cell death (Bingham et al., 2005). This could either contribute to the loss of the neurogenic cells or may represent an early signaling event to initiate proliferation. In a rodent model of transient ischemia, reperfusion resulted in a transient decrease in *Hes5* mRNA levels with a concurrent increase in *Mash1* mRNA levels (Kawai et al., 2005).

32.6.4. Traumatic Brain Injury

Permanent structural changes occur in the brain following a traumatic brain injury (TBI) yet often there is remarkable functional recovery. This is more than likely due to a number of repair mechanisms including altering the connectivity of the remaining neurons and possibly the generation of new neurons. The general cellular characteristics that occur with TBI include a diffuse pattern of cell death. This is accompanied by an intense inflammatory response from both the resident microglia and from infiltrating cells such as monocytes, macrophages, T-cells, and neutrophils, given the damage to the blood brain barrier (Ghirnikar et al., 1998; Raivich et al., 1999). A secondary wave of neuronal death involves what is commonly referred to as delayed neuronal death. Reactive gliosis occurs in the lesion site and the astrocytes form a glial barrier to contain the injury. Thus, TBI results in the upregulation of numerous factors within the lesion site and possibly at more distant non-directly-injured sites, including cytokines, chemokines, and trophic factors. Neurogenesis can be triggered by targeted apoptotic death in cortical neurons (Magavi and Macklis, 2001) and TBI of the cortex can trigger increased proliferation of cells within the SGZ of the DG (Dash et al., 2001; Kernie et al., 2001). At the site of lesion, induction of the transcription factor, *Olig2*, is a common feature with a significant increase in the number of *Olig2*-positive cells occurring in multiple nervous system regions (Buffo et al., 2005). During development *Olig2* is expressed in neuroepithelial cells, motoneuron precursors, and differentiating oligodendrocytes. It also plays a role in transit-amplifying precursors in the adult subependymal zone. It is possible that upon physical injury or under inflammatory conditions, *Olig2* expression may mediate dedifferentiation of glial cells and

regulation of neuro/gliogenesis in the brain (Cassiani-Ingoni et al., 2006).

32.6.5. Chemical Injury and Damage to Dentate Granule Neurons in the Hippocampus

Neurogenesis induced in both the SVZ and the SGZ have been examined in animals of various ages following drug or chemical induced injury. Excitotoxicity induced by a direct injection of the glutamate analog, alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA), into the cerebral ventricle of the brain will induce the generation of immature neurons from the SVZ in immature rat pups (Xu et al., 2005). Postnatal excitotoxicity induced by an injection of NMDA into the sensorimotor cortex differentially affected proliferative cells in each of the zones with a decrease of BrdU+ cells in the RMS yet, an increase of labeled cells in the striatum. In the SGZ, this injection and injury did not alter the proliferative nature or level of the cells (Faiz et al., 2005). This finding suggests that different stimuli, location, or level of damage are required to induce proliferation in each of the two regions. Adult hippocampus neurogenesis may be regulated by NMDA receptors present in precursor cells and in newly differentiating granule neurons suggesting an additional property of these receptors in the adult comparable to the critical role during brain development (Nacher and McEwen, 2006; Nacher et al., 2007).

The majority of experimental brain injury models have focused on established models of seizure, ischemia/hypoxia, or traumatic brain injury. However, given that the greatest proportion of cells produced from the SGZ are cells in close proximity, the dentate granule neurons a few studies have been undertaken to examine neurogenesis following a focal injury to this region. Death of dentate granule neurons has often been attributed to apoptotic mechanisms in various animal models. Of these models, adrenalectomy (Nichols et al., 2005), bacterial meningitis (Bogdan et al., 1997), and trimethyltin (Brucoleri et al., 1998; Geloso et al., 2002; Lefebvre d'Helencourt and Harry, 2005) show damage localized to the dentate granule neuron and evidence for the induction of proliferation in the SGZ as a mechanism of neural repair. Tauber et al. (2005) reported an increase proliferation and differentiation of neural progenitor cells in the SGZ after bacterial meningitis. This was accompanied by an increased synthesis of BDNF and TrkB, a decrease in NGF mRNA levels, and no changes in GDNF at 30 h following transmittal of the infection. Adrenalectomy has served as a model to examine glucocorticoid regulation in the hippocampus and induces neurogenesis in the dentate gyrus (Fischer et al., 2002; Nichols et al., 2005). Other models of glucocorticoid regulation support a role for this signaling pathway in hippocampal neurogenesis. The trimethyltin model is somewhat unique in the specificity for the dentate granule neurons. This specificity does not appear to be related to glucocorticoid signaling, excitotoxicity, or ischemia but rather, may

be related to localized inflammation, oxidative stress, and altered calcium regulation. The timing of neuronal death follows that of “delayed neuronal death” seen with seizure, in that pronounced neuronal death occurs within 24–48 h of a systemic injection of the compound. The initial report of neurogenesis induced by prototypical neurotoxicant trimethyltin (TMT)-induced dentate gyrus degeneration suggested the active period of neural precursor proliferation coincided with the active period of neuronal death and the induction of pro-inflammatory cytokines (Harry et al., 2004). This was followed by two supporting studies in rat (Corvino et al., 2005) and adult mouse (Ogita et al., 2005). In the rat, the primary target site is not the dentate granule neurons but rather the CA 3–4 pyramidal neurons and requires 5–6 days for damage to be clearly evident. In this model, at 14 days, BrdU uptake was seen in NeuN positive cells in the dentate gyrus but co-localization was not yet evident in the CA3–4 region suggestive of undifferentiated cells at this early time point. In the adult mouse, Ogita et al. (2005) reported that the BrdU+ cells that co-expressed NeuN were located not in the SGZ or the granule cell layer but rather in the molecular layer and the hilus. This is in contrast to the data in the weanling mouse (Harry et al., 2004) where co-localization of these two markers was not prominent in these peripheral areas but rather, localization was seen in the dentate granule cell layer. These data suggests that the temporal and spatial progression of neurogenesis following a localized damage to the dentate granule neuron is dependent upon age, level of damage, and localized environmental cues including those associated with a neuroinflammatory response.

32.7. Neuroinflammation

During development, mesodermal cells committed to the macrophage cell lineage infiltrate the CNS to become resident microglia that actively engulf apoptotic neurons (Cuadros and Navascules, 1998). The phagocytosis of apoptotic cells is a process to remove the cellular debris thus, preventing leakage of potentially cytotoxic or antigenic substances. With brain trauma, both the resident microglia and infiltrating monocytes comprise the macrophage population in areas of direct injury and traumatic necrosis of neurons. With transient ischemia, activated microglia are detected as early as 20 min post reperfusion and actively phagocytize the neuronal debris at 24 h. The impact on the neuron of microglia reactivity to an insult and activation to a phagocytic phenotype remains a question. The influence of each of these microglial phenotypes on newly generated neurons is an even greater unknown. In the activated state, microglia can reduce neurogenesis (Monje et al., 2003; Ekdahl et al., 2003). However, microglia activated by interleukin (IL)-4 or interferon gamma can induce the production of neurons or glia from adult progenitor cells (Butovsky et al., 2006). In every injury model the induction of “neurogenesis” is accompanied by a microglial response that may be a source

of neurogenic factors. Given their location within the injury, microglia would be in a prime position to provide such signals to the new neurons such as IGFs, EGF, and TGF- β 1 (Banati and Graeber, 1994). Microglia also secrete IL-1 that stimulates astroglia hypertrophy and promotes nerve growth factor synthesis by non-neuronal cells (Heese et al., 1998). In addition to monocytes, activated T cells can cross the blood brain barrier and penetrate the CNS (Flugel and Brandl, 2001) and, with appropriate signals, secrete Th2/3 and neurotrophic factors such as, interleukin-10, TGF- β and BDNF (Aharoni et al., 2003). Thus, multiple cells can provide regulatory molecules to the new neurons at a critical time in the injury process.

Summary

The current data demonstrates that the adult brain retains the capacity to generate new neurons. The exact role for these cells, their mechanism of integration into the existing cytoarchitecture, and their ability to restore function following injury remain a basis for extensive ongoing basic research and targeted efforts to identify their therapeutic potential for brain repair (Sohur et al., 2006). The progenitor/stem cell populations in the brain are exposed to multiple signals at the time of origin, during migration, and at the site of differentiation. Distinct signaling pathways that act on a multipotent progenitor cell might inhibit or modulate each other leading to interactive signals and biological processes. The question remains as to how the cells integrate the different extracellular signals present in the injury environment to provide for a successful repopulation of the damaged region.

Review Questions/Problems

- 1. What is a primary neurogenic region and target site of the adult brain**
 - a. the subventricular zone to the olfactory bulb
 - b. the subventricular zone to the rostral migratory stream
 - c. the subgranular zone to the rostral migratory stream
 - d. the subgranular zone to the pyramidal cell layer of the hippocampus.
- 2. What types of stimuli have been shown to enhance basal levels of adult neurogenesis?**
 - a. physical exercise
 - b. enriched environment
 - c. visual recognition
 - d. A and B
- 3. Progenitor cells are distinguished from stem cells by their**
 - a. ability to self-renew
 - b. multilineage differentiation
 - c. inability to self-renew
 - d. B and C

4. In the adult rodent brain, doublecortin has been used to identify

- a. mature neurons
- b. oligodendroglia
- c. immature neurons
- d. stem cells

5. There are both stimulatory and inhibitory factors for proliferation of neural stem/progenitor cells. Which is an inhibitory factor

- a. Fibroblast growth factor
- b. Transforming growth factor – beta2
- c. Bone morphogenetic proteins
- d. olfactory marker protein

6. Nestin is a marker for

- a. mature glia
- b. immature neurons
- c. immature neurons and reactive glia
- d. olfactory neurons

33.1. Introduction

Neurology is a discipline rich in the study of inherited disorders. Most of these studies have focused on diseases in which changes in a single gene are severe enough to cause a disease by themselves. Examples of such changes are mutations in the dystrophin gene that lead to Duchenne muscular dystrophy, or triplet repeat expansions that lead to Huntington disease. However, as well-known as these examples are, they do not reflect the majority of the diseases that the average physician experiences in his or her practice. Most common disorders have important genetic components, but they are not as obvious. Rather, each contributes a smaller amount of risk, and may require environmental interactions to produce symptoms. The elucidation of these genetic elements has the potential to radically change the way all physicians practice medicine in the future. In this chapter we will begin to explore the nature of these genetic changes (complex genetics) and current knowledge of their contribution to several common neurodegenerative disorders.

33.2. Background

Genetic disorders produced by a single causal gene, such as our example of dystrophin mutations leading to Duchenne muscular dystrophy, are termed “Mendelian” disorders, after the Austrian monk Gregor Mendel (1822–1884), who discovered unitary inheritance in pea plants. There are three primary types of Mendelian inheritance. First, dominant genetic variants or alleles produce a trait or disease if one copy of the allele is sufficient to cause the disease (e.g. Huntington disease). Sec-

ond are recessive variants, which are only observable if two copies of the disease allele are inherited, generally one from each parent (e.g. Friedrichs ataxia). Third are genes on the X-chromosome producing X-linked traits that may act in either a dominant or recessive fashion. The distinguishing feature of X-linked traits is that a recessive variant will appear to act dominantly in males who each have only one X chromosome and therefore only one allele (e.g. Duchenne muscular dystrophy). In contrast, complex traits are governed by an interaction of multiple genetic variants (polygenic) or multiple genetic variants with or without environmental influences (multifactorial). In a complex disease, the contribution from a single gene is not enough to cause the disease, but does make a person more susceptible. Thus, they are known as susceptibility genes. Any variation in DNA (base pair change, deletion, duplication, or expansion) that occurs at a single location is termed an allele. Allelic mutations so severe that they cause disease by themselves are termed mutations. Variations that are neutral or do not cause disease by themselves are termed polymorphisms. Traditionally, polymorphisms were defined as genetic variations appearing in greater than 1% of the population under investigation. However, with modern techniques, we now know that rarer polymorphisms exist, and so this frequency definition is no longer useful.

The most common currently used polymorphisms are single nucleotide polymorphisms (SNPs), i.e., a variation of a single base pair (usually with only two alleles). They are quite numerous, often every 500–1000 base pairs. Initially, SNPs were difficult to detect easily. In the 1980s only a specialized subset of SNPs, the restriction fragment length polymorphisms (RFLPs), could be practically utilized in studies. RFLPs are defined by short sequences of DNA (four to eight bases) that contain a SNP that is recognized and cut by a specific DNA restriction endonuclease. The SNP variation will either create or eliminate the cutting site. The differing lengths of DNA may then be detected using electrophoresis. When the technique of polymerase chain reaction (PCR) was applied to microsatellites, they became the polymorphism of choice for disease studies (Eisenstein, 1990). Microsatellites contain a

variable number of repeating elements (usually di- or tetra-nucleotide repeats) that are highly polymorphic and widely distributed through the genome, although much less common than SNPs. Using unique sequences surrounding a microsatellite, PCR is able to specifically amplify the DNA region containing the microsatellite. Since the microsatellites vary in size, they can then be separated on electrophoretic gels. Finally, the continued development of technology has brought the field of genotyping full circle, so that we can now easily genotype all SNPs, providing millions of polymorphisms for use in research. The ultimate genotyping will be total human genome sequencing, which in 2006 costs ~10 million dollars per individual. However, technology is progressing to reduce this cost. Current NIH funded projects seek technology that will bring the "\$1000" genome to a reality.

The degree or the proportion of variation that is directly attributable to a genetic etiology is termed heritability. It is the ratio of the genetic variance of a trait (e.g. height, blood pressure, body mass index, etc.) to the total phenotypic variance found in a population for that trait. Complicating the evaluation of genetic effects is penetrance. The term penetrance was introduced when molecular and clinical tools were not as sensitive as they are today. Penetrance is an "all or none" phenomena; if something is non-penetrant it was thought that the disease may not manifest in every individual who has the causative genetic variant. With today's improved tools of disease detection, the concept of penetrance is not as useful, as in many cases we can detect some signs or features associated with the disease. Expressivity is generally a more useful concept and refers to variation among affected individuals in severity or manifestation of the disease phenotype. Penetrance and expressivity of causative variants should not be confused with susceptibility in polygenic or multifactorial complex diseases. Finally, the relative risk (λ) is the risk of the disease in first degree offspring of an affected individual relative to the risk of the disease in the general population. Any value of $\lambda > 2$ is considered evidence for a genetic contribution.

The approach used to study a genetic disease depends on available technology and the population under investigation. SNP genotyping is now the least expensive and most reliable technology, so it has become the most common method. However, there are still instances when highly polymorphic microsatellites (often in combination with SNPs) can provide more detailed information in select regions of the genome. Most study designs break down into two types, family-based and case-control. There are several different family-based approaches. Twin studies provide an opportunity to tease apart genetic and familial environmental contributions. The concordance of disease phenotype can be compared between monozygotic and dizygotic twins. Since monozygotic twins share all of their genome while dizygotic twins share on average half of their genomes, greater disease concordance among monozygotic twins is consistent with a genetic component to disease. Limitations to twin studies include difficulty in obtaining reasonable sample sizes, vulnerability to assump-

tions about shared environments, inability to account for potentially different prenatal environments, and the need to sex and age match the already limited twin groups. Generally, more power and larger samples are needed to localize genes contributing to disease.

A more powerful family-based approach is linkage analysis. Linkage analysis utilizes genetic polymorphisms to determine if a physical region of the genome is inherited along with a trait or disease. Multigenerational families with multiple sampled affected and unaffected individuals are efficient for linkage analysis. However, collection of samples with reliable clinical and phenotypic data may be difficult or impossible in some cases, especially for later onset disorders. Sibling pair designs offer another family-based alternative, and siblings are generally more widely available. These family-based methods rely on identification of polymorphisms that co-occur with disease in families more than we would expect by chance. If a polymorphism travels with disease, then we can conclude that it is likely to be physically near to the gene causing the disease. Sophisticated computer programs are able to account either linkage or association within family-based studies. The difference between linkage and association is often confusing to those beginning the study of complex genetics. Linkage implies causality for a physical region of a chromosome, but not for any particular gene or variation within that region. This is different from association, which implicates a specific allele or variation in that region as statistically coupled to the disease. Association may be due to either (1) true causal association with the disease, or (2) linkage disequilibrium (LD). A marker in LD is so close to the disease locus that recombination or mutation has not yet significantly interrupted its co-inheritance with the disease allele within the population under study. Thus a SNP traveling in a population on the same small piece of DNA as the disease gene (in strong LD) can act as a surrogate for the presence of the actual disease change. LD is measured as one of two terms, the correlation coefficient r^2 , or D prime, which are derived independently. The correlation coefficient is usually easier to understand, and has become more commonly used in recent years. The term "linkage disequilibrium" is derived from the fact that physically proximate DNA variations (i.e. tightly linked) do not follow the expectations of Hardy-Weinberg equilibrium (which assumes independent segregation), and thus the variations are in Hardy-Weinberg "disequilibrium." Two polymorphisms in strong LD are inherited together forming a haplotype.

As human genetics moves forward, it relies more heavily on genetic association studies to identify genes contributing to the susceptibility of common disorders and pharmacogenetic interactions (genetic variations that affect any biological interaction with a drug). There are two types of association studies. Case-control studies compare allele frequencies in a set of unrelated affected individuals to those in a set of matched controls. The control populations should be matched with respect to ethnicity as well as other factors such as age. Spurious associations may result from

unrecognized population stratification i.e., the existence of multiple population subtypes in what is assumed to be a relatively homogeneous population. Unlike case-control studies, where the unit being studied is the individual, family-based association studies use the individual alleles in a person as the unit to be investigated. Family-based studies control for the possibility of genetic differences between the case and control populations (i.e., stratification) by comparing the frequencies of alleles transmitted to the affected child to the alleles not transmitted. While statistically not as powerful as case-control studies, the ability to greatly reduce this stratification error has led many investigators to prefer family-based designs.

Essentially there are three different research approaches to identifying a disease gene: candidate gene analysis; positional cloning; and the most recent, whole genome association analysis. There are advantages and disadvantages to each. Candidate gene analysis is potentially the fastest, but also the least likely to have success. It assumes that one understands the pathophysiology of the disease, which in most cases one does not. Therefore, it has historically been very inefficient overall. Positional cloning is a “genomic” approach that is unbiased towards the causality of the disease and has been extremely successful. Its strength lies in the use of the fundamental mathematics and the known biology of DNA, i.e., the properties of inheritance. The investigator collects family data and then identifies the location of the disease gene through linkage studies. Then, using a combination of molecular genetics and mathematical genetic techniques, the investigator can identify the genetic change that differentiates the affected from the unaffected individuals. Its disadvantages are that it is more expensive, requires multidisciplinary collaborations, and can take many years. However, its advantages are that it will eventually provide the desired results, it is nonbiased requiring no previous understanding of the disease process, and it will find new, unknown genes. It also handles genetic heterogeneity very well, and thus it is the preferred approach for most investigations. Positional cloning has indeed been the main “engine” that has fostered the genetic revolution in medicine. Whole genome association is very new, and involves simultaneously genotyping a huge number of DNA variations (100,000–500,000 polymorphisms), bypassing linkage analysis, to directly identify the associated genetic variation. It does not require the family-based data that linkage analyses do. While potentially rapid, it is very expensive and its practical value is currently unknown. Genomic convergence (Hauser et al., 2003) describes a rapidly developing evidenced-base approach to designing and evaluating genetic studies. Essentially, candidate genes are prioritized by the number of independent methodologies that support that gene’s role in a given disorder. For instance, a whole genome or regional linkage analysis, previous association studies, gene expression studies, as well as evidence from model systems are combined to direct efforts towards those candidates that are most likely to play a significant role in the disease. In addition to identifying

those genes that alter susceptibility to disease, we now recognize the importance of modifier genes. A modifier gene effects the phenotypic expression of another gene. The symptoms of many inherited diseases vary widely, even between members of the same family. Severity, age at onset, and symptom profiles may be different for individuals carrying identical genetic mutations. This effect is well known in rodent models, where the homozygous background of different strains can radically alter phenotype.

33.3. Neurodegenerative Disorders

33.3.1. Alzheimer’s Disease

Alzheimer’s disease (AD) is characterized by an insidious onset and progressive deterioration of memory and at least one other cognitive function (language, praxis, recognition, or executive functioning). It is the leading cause of dementia in the elderly, affecting more than 4.5 million people in the United States (Hebert et al., 2003). Prevalence is strongly dependent upon age.

Several lines of evidence pointed to a genetic diathesis for the development of AD. Initial familial aggregation studies demonstrated clustering of AD within families (Sjogren et al., 1952; Heyman et al., 1983; Nee et al., 1983). Twin studies also demonstrated a genetic component to AD. The concordance rate among monozygotic (identical) twins is significantly higher than the concordance rate among dizygotic twins who on average share only half of their alleles (Breitner et al., 1993; Bergem, 1994; Breitner et al., 1995; Bergem et al., 1997).

33.3.1.1. *Mendelian Genes of Early-Onset Alzheimer’s Disease (EOAD)*

Linkage analysis, followed by positional cloning of candidate genes, was used to identify genetic variants of the three genes that are known to cause early-onset familial AD. The three known AD-causative genes are: amyloid precursor protein (APP) (Goate et al., 1991), presenilin I (PS1), and presenilin II (PS2) (Levy-Lahad et al., 1995; Rogaev et al., 1995; Sherrington et al., 1995; Rogaev et al., 1995; Sherrington et al., 1995). Each of the identified mutations is associated with autosomal dominant inheritance within the affected families.

The APP gene was the initial identified gene, localized to chromosome 21 in 1987 (Goldgaber et al., 1987; Tanzi et al., 1987, 1987). Chromosome 21 was an intriguing location, since Down syndrome patients develop the pathologic signs (neuritic plaques and neurofibrillary tangles) and symptoms of AD at an early age (Lemere et al., 1996). Mutations in APP appear to cause shifts in the proteolytic cleavage of APP toward amyloidogenic pathways. In addition, APP mutations lead to excessive production of the 42 amino acid residue of beta-amyloid. This 42 residue beta-amyloid ($A\beta_{42}$) is less

soluble than the alternative 40 residue isoform ($A\beta_{40}$) (Suzuki et al., 1994), and is associated with increased aggregation and neurotoxicity (Hilbich et al., 1991). Worldwide, only about two dozen families have been described carrying mutations of the APP gene.

Subsequent studies in additional AD families with autosomal dominant inheritance demonstrated linkage to chromosome 14 (Schellenberg et al., 1992; St George-Hyslop et al., 1992; Van Broeckhoven et al., 1994; Van Broeckhoven et al., 1994). This led to the identification of the PS1 gene as the cause in these families (Sherrington et al., 1995). Since then, more than 150 different PS1 mutations scattered throughout the gene have been described. Phenotypically, PS1 familial AD is the most aggressive form of AD, and affected individuals generally have disease onset in their fourth or fifth decade of life.

After characterization of APP and PS1, many of the remaining unlinked families originated from the Volga river basin of Russia (Bird et al., 1988), and showed linkage to chromosome 1 (Levy-Lahad et al., 1995). Serendipitously with the cloning of the PS1 gene, a larger 7.5 kb alternative polyadenylation message was identified. The product represented a gene homologous to PS1. The new gene, PS2, was mapped to the known linkage region on chromosome 1, and was found to have the mutation in these families.

Like APP mutations, the PS1 and PS2 mutations can lead to increased levels of $A\beta_{42}$ in the brain. Whether the presenilins interact directly with APP through their putative γ -secretase activity, or act as co-factor for another γ -secretase, remains unclear. Furthermore, the relationship between identified causal mutations and AD phenotype is not necessarily simple. For example, PS1 mutations associated with familial early-onset AD have been identified in individuals with frontotemporal dementia who have no evidence of the $A\beta$ accumulation characteristic of AD.

While variants in these three genes (APP, PS1, and PS2) account for between 30% and 50% of early-onset familial AD, overall they account for less than 2% of all cases of AD (Klaver et al., 1998; Finckh et al., 2000; Liddell et al., 1995; Rosenberg et al., 2000).

33.3.1.2. Late-Onset Alzheimer's Disease (LOAD) and Susceptibility Genes

LOAD patients comprise the majority (90–95%) of individuals afflicted with AD. The prevalence of LOAD increases exponentially with advancing age (Rocca et al., 1991). The relationship between LOAD and the first universally accepted susceptibility gene, Apolipoprotein E (ApoE), was initially discovered using linkage analysis in a subset of AD patients with an age-at-onset greater than 60 (Pericak-Vance et al., 1991). In today's rush to gather larger and larger datasets, it is important to realize that only 33 families were used in this initial analysis, reflecting the strength of ApoE's genetic effect in AD. The ApoE gene lies on the long arm of chromosome 19 (19q13.2) coding for a serum protein involved in

the transport, storage, and metabolism of lipids. ApoE in the central nervous system is synthesized by astrocytes (Mahley, 1988). There are three common isoforms for ApoE protein: ApoE2, ApoE3, and ApoE4. These three isoforms result from single amino acid substitutions at two different amino acid residues, 112 and 158 (Weisgraber et al., 1982; Rall et al., 1982). Therefore, the ApoE alleles are actually haplotypes.

The role of ApoE in cardiovascular diseases has been well-documented, and since the initial discovery of its association with AD it has also been shown to be associated with multiple neurodegenerative diseases in a growing number of studies. The ApoE4 allele has consistently been associated with risk for sporadic and familial LOAD, whereas, the ApoE2 allele is inversely associated with risk for LOAD (Corder et al., 1994). The relative risk for LOAD for ApoE4 homozygotes and for ApoE3/4 heterozygotes are ~15 and 3, respectively, compared to ApoE3 homozygotes. A meta-analysis of 40 studies by (Farrer et al., 1997), demonstrates that the effect of ApoE4 allele is weaker in the African-American and Hispanic populations, compared to the Caucasian population, while the effect of ApoE4 allele is greater in the Japanese population, compared to Caucasian individuals. The reasons for this are not clear but may reflect differences in modifier genes.

While ApoE is critically important, it does not account for all of the genetic variation seen in AD. The heritability of AD has been estimated at about 80% (Bergen, 1994), but more than a third of AD cases do not have a single ApoE4 allele. The sibling relative risk (λ_s) for the ApoE locus is estimated to be about two, and Farrer et al. suggested that ApoE accounts for, at most, 50% of the total genetic effect in AD (Farrer et al., 1997). To date, efforts to identify the remaining AD loci are ongoing.

Variants in more than 200 candidate genes have been tested for association, and variants in 115 genes are reported to be associated with late-onset AD. However, other than ApoE, no candidates have achieved wide support. Several factors account for the difficulties undermining these studies. Most studies have been undersized, the level of genomic detail is small, and locus heterogeneity reduces the statistical impact of any single genetic variant under investigation. Together these elements conspire to make replication or confirmation difficult even if genuine effects are identified. Indeed, recent theoretical work has confirmed what most applied researchers already knew, that validation of association with additional data is more useful than actual separate replication studies (Skol et al., 2006).

Several linkage analyses for LOAD have been published. The most frequently linked chromosomes are 9, 10, and 12. Significant linkage was identified on chromosome 9p using a North American LOAD dataset (Pericak-Vance et al., 2000). Farrer confirmed the linkage to chromosome 9p in a consanguineous Israeli-Arab sample, suggesting a possible autosomal recessive locus (Farrer et al., 2003). In another independent dataset, the linkage signals on 9p and 9q were both confirmed (Kehoe et al., 1999; Myers et al., 2002; Blacker et al., 2003).

However, the actual genetic variants producing the linkage signals remain elusive.

Myers conducted a two-stage genome-wide linkage scan and found linkage to a marker on chromosome 10q (Myers et al., 2000). Subsequently, Ertekin-Taner treated plasma A β concentration as a quantitative phenotype and detected linkage to a quantitative trait locus close to the candidate gene α -T catenin on 10q (Ertekin-Taner et al., 2003). Additionally, GSTO1/2 has been identified as an age-at-onset modifier in AD (Li et al., 2003). However, no well replicated candidate gene affecting risk for AD has been identified on chromosome 10.

After the first report identifying linkage evidence on chromosome 12p (Pericak-Vance et al., 1997), several follow-up studies have produced mixed results in this region as well as another region on 12q (Pericak-Vance et al., 1997; Pericak-Vance et al., 1998; Scott et al., 2000; Scott et al., 1998). The mixed findings may be attributable to genetic heterogeneity. Scott found linkage evidence suggesting genetic heterogeneity since some families clustered on a smaller region of chromosome 12 and at least one affected individual had Lewy-body dementia but lacked the ApoE4 allele (Scott et al., 2000). Other studies confirmed a risk effect as well as an age-at-onset effect in families that lack the ApoE4 allele (Wu et al., 1998; Mayeux et al., 2002).

Chromosome 12p contains several candidate genes, including the α -2 macroglobulin and DLD receptor related protein-1 genes, which are related to β -amyloid metabolism. However, association studies on these candidate genes have produced conflicting results. Convergent linkage and association evidence has been reported for the glyceraldehyde-3-phosphate dehydrogenase (GAPD) gene on 12p (Li et al., 2004b) but the results could not be replicated in an independent dataset. In short, evidence for susceptibility genes on chromosome 12 remains elusive with conflicting findings, which may in part be due to genetic heterogeneity.

33.3.1.3. *Modifier Genes of LOAD*

In addition to increasing susceptibility risk for AD, the ApoE gene on chromosome 19 also appears to have modifier effects on the age-at-onset of AD. In one family-based study, the estimated mean age-at-onset for subsets consisting of individuals carrying no ApoE4 allele, one copy of the ApoE4 allele, and two copies of the ApoE4 allele, are 84.3, 75.5, and 68.8 years, respectively (Corder et al., 1993). Additionally, while the ApoE4 allele is a risk factor for LOAD in nearly every population, the magnitude of association between the ApoE4 allele and LOAD may vary by ethnicity.

Although no candidate genes on chromosome 10 have been reported to be significantly associated with risk of LOAD, the Glutathione S-transferase omega-1/2 complex (GSTO1/2) has been associated with variation in age-at-onset of both LOAD and Parkinson disease (Li et al., 2003, 2005). Using a very large pooled AD and PD dataset, Li et al. used linkage analysis to demonstrate overlapping linkage peaks in both

disorders. Using gene expression and genomic convergence with the linkage data, Li et al. demonstrated that four genes differentially expressed between AD and control hippocampi were located in the chromosome 10 age-at-onset linkage peak (Li et al., 2003). One of these genes (GSTO1) was highly associated with age-at-onset, as was its homologue, GSTO2, which lies immediately next to it. Subsequent research demonstrates that this association is responsible for the linkage peak but only appears to have its effect in about 25% of AD families, shifting the age-at-onset an average of 8 years in these families (Li et al., 2006). This successful use of genomic convergence is also an excellent demonstration of genetic heterogeneity in both AD and PD. The functions of GSTO1 are not well understood (Board et al., 2000). The Ala140Asp and Thr217Asn variants of GSTO1 display reduced enzyme activity (Tanaka-Kagawa et al., 2003) and therefore might influence the susceptibility to oxidative stress. Recent data suggest that GSTO1 is involved in the post-translational modification of the inflammatory cytokine Interleukin-1 β (Laliberte et al., 2003) and therefore contributes to inflammation. This is provocative given reports of the possible role of inflammation in AD and PD (McGeer and McGeer, 2004). Subsequently, four additional case-control studies have been reported for GSTO1 and age-at-onset in AD. One found no age-at-onset effect in Japanese (Nishimura et al., 2004). Lee et al. genotyped only one SNP in GSTO1 and found a weak association for risk of AD in Caribbean Hispanics but not for age-at-onset (Lee et al., 2004). Ozturk reported identical findings in a large Caucasian sample (Ozturk et al., 2005). Kolsch studied GSTO1 in stroke patients and found it was associated with an increase risk for stroke, and also found a mild age-at-onset effect in AD (Kolsch et al., 2004). These present excellent opportunities to discuss some of the difficulties in interpreting association studies. Three of the studies were small, and if only 25% of the AD population is affected (as suggested by Li et al.), then validation of the effect will require large datasets. Li et al. used a family-based design, but the other studies were all case-control. This may be a major point, since the more common background in family-based studies may enable them to be more sensitive at detecting specific gene modifiers. Finally, the difference between a modifier gene and a risk gene may be attributed more to sample selection than anything else. For example, if a sample has primarily earlier age-at-onset cases, then a gene that makes cases fall into that group will be seen as a risk gene.

33.3.1.4. *Clinical Implications of Genetic Discoveries for AD*

Two broad categories of individuals may present for genetic counseling in AD. Family members are either symptomatic (demonstrating disease symptoms and signs) or are considered presymptomatic and at risk. Application of genetic tests to symptomatic patients seeks to confirm a diagnosis or provide specific mutation information to a family. As its name

suggests, presymptomatic testing is for individuals who are currently healthy, but undergo genetic testing to provide information on the likelihood they will get the disease in the future. At present, counseling remains quite controversial in complex disorders since the presence of a single positive test does not provide a clearly defined risk for a single individual. The best example is ApoE and AD. Perhaps more importantly, without useful preventative treatments for such diseases as AD, the justification for testing remains elusive for many clinicians. Thus, we are at an uncomfortable time in medical history, a true “catch 22” since (1) we must know the causes of common diseases to efficiently treat them, (2) this knowledge raises anxiety and suggests risks for asymptomatic individuals, but (3) we have no treatments once we identify these genes. Obviously the hope is that preventative therapies will come quickly once the genetic risk factors are identified.

Currently, genetic counseling for AD families has followed the Huntington disease model recommended by the Canadian Collaborative study (Copley et al., 1995). Generally, high-penetrant mutations, such as PS1, APP, and the Tau gene (for fronto-temporal dementia), appear to serve as better candidates for genetic screening of AD in at-risk families, than low-penetrant mutations, such as PS2 and ApoE (George-Hyslop and Petit, 2005). However, several studies have now been published examining genetic testing for the ApoE4 allele in presymptomatic individuals, with generally very positive results (Drzezga et al., 2005).

33.3.2. Parkinsonian Disorders

33.3.2.1. *Parkinson's Disease*

Like AD, theories underlying the pathogenesis of Parkinson disease (PD) have evolved since it was first described by James Parkinson in 1817. PD is a neurodegenerative disorder that affects the dopaminergic neurons of the CNS, most notable by the degeneration of cells in the substantia nigra. The primary clinical triad is resting tremor, rigidity and bradykinesia, although many of the non-motor symptoms are also problematic for the patients. Originally believed to be primarily an environmental disease, it is now known to have a strong genetic component. Like AD, the genetic components of PD are split between Mendelian and susceptibility genes. However, several common themes are arising from genetic investigations, notably the importance of mitochondrial dysfunction and inflammation in the pathogenesis of the disorder.

33.3.2.1.1. Mendelian Genes

Most interest in the field has focused on a few Mendelian genes that lead to PD, though it is believed these represent only a small portion (perhaps 10%) of the 1.5 million PD patients in the US. The two most common Mendelian genes are Parkin, on chromosome 6 and Leucine-Rich Repeat kinase 2 (LRRK2) on 12q12. Additionally, less common genes have been identified including DJ1, PINK1, and α -Synuclein.

α -Synuclein: The α -Synuclein gene was the first gene found to have mutations causing PD. However, it remains a rare cause of the disease affecting only a few families. Identification of α -Synuclein's role was relatively straight forward in these families since the large gene triplication followed an autosomal dominant mode of inheritance. It is unclear if more subtle single nucleotide variants contribute to disease in the broader population.

Parkin: Parkin was discovered in juvenile PD (age-at-onset <40 years.) families in Japan using positional cloning techniques. It was quickly realized that this form of PD was not just limited to Japan but was a major contributor to juvenile PD throughout the world. In addition, while the mean age-at-onset of Parkin homozygotes is about 20 years, the age-at-onset distribution is wide, with the oldest age-at-onset reported at 80 years. Thus, Parkin should not be thought of as merely an “early-onset” PD gene but considered in all PD patients with a strong family history.

Parkin is located on the outer mitochondrial membrane, and early research identified it as an ubiquitin E2 ligase, suggesting abnormal protein degradation as its likely mechanism of disease. Recent evidence suggests it is important in the expression of mitochondrial proteins encoded by the mitochondrial genome. Gene expression data also found that mtDNA encoded mitochondrial proteins had increased expression in PD patients versus controls, when compared to their nuclear encoded counterparts (Noureddine et al., 2005). This is also consistent with the van der Walt report of a mtDNA haplogroup association in PD (van der Walt et al., 2003). The initial findings of van der Walt have been confirmed in multiple studies (see below), and raise another possible disease mechanism for Parkin, given the increasing evidence for the importance of mitochondria in PD.

Leucine Rich Repeat Kinase 2 (LRRK2): mutations lead to late-onset PD, in an autosomal dominant pattern, with variable age-at-onset. To date, the S2019G mutation is by far the most common (>50%) and appears to have arisen at different times in the past. However, the biological function of LRRK2 is currently not known.

33.3.2.1.2. Susceptibility Genes

Genomic Linkage in Parkinson Disease: To date, four complete genomic screens have been reported for PD (Scott et al., 2001; Destefano et al., 2001; Pankratz et al., 2002; Hicks et al., 2002). Three linkage screens for age-at-onset genes affecting PD have thus far been performed (Li et al., 2002; Destefano et al., 2002; Pankratz et al., 2004). The most interesting finding is on chromosome 1p, where the age-at-onset linkage peak of Li et al. (Li et al., 2002) is very similar to the risk linkage peak (PARK10) in late-onset Icelandic PD families (Westerman et al., 1999). There is also overlap between the age-at-onset and risk linkage peaks on **chromosome 9q from the GenePD Study** (Destefano et al., 2001; Destefano et al., 2002). It is conceivable that a single gene is influencing

both risk and age-at-onset (Apolipoprotein E, for instance, is known to affect both risk and age-at-onset of PD, see below) (Li et al., 2004a), but it is also possible that distinct susceptibility and age-at-onset alleles exist at each one of these loci.

FGF 20: Fibroblast growth factor 20 is a member of the large family of FGF growth factors. It lies within the chromosome 8 linkage peak identified by Scott et al. (Scott et al., 2001) and is notable because it is critical to the culture of dopaminergic neurons derived from embryonic stem cells. In addition, unlike GDNF and BDNF, which are ubiquitous in the CNS, FGF20 is primarily expressed in the substantia nigra, suggesting it has a highly specific relationship with dopaminergic neurons in the brain. van der Walt found strong association of FGF20 alleles and risk for PD (van der Walt et al., 2004). The allelic association was recently validated by Clarimon (Clarimon et al., 2005).

Tau: is a microtubule-associated protein that functions in the assembly and stability of the microtubule. Mutations in Tau are known to cause frontotemporal dementia with Parkinsonism-17 (Hutton et al., 1998). Two different groups initially reported that an intronic microsatellite allele, A_0 , was associated with PD (Pastor et al., 2000; Golbe et al., 2001). Oliveira et al. also found association of this allele with PD. Furthermore, it lies under the chromosome 17 peak from a genomic linkage screen, (Scott et al., 2001) supporting its likely importance in PD (Martin et al., 2001). Healy et al. performed a meta-analysis of nine case-control studies plus their own and confirmed that the H1 haplotype (containing the A_0 allele) was highly associated with PD ($p < 10^{-6}$) (Healy et al., 2004). Oliveira demonstrated that the H1 haplotype is extremely large, due to extensive linkage disequilibrium in the region (Oliveira et al., 2004). In fact, the linkage disequilibrium is so large that the H1 haplotype encompassed 3.15 megabases and contains other genes besides Tau, including Corticotropin-releasing Hormone Receptor 1, Presenilin Homolog 2, Saitoin, and KIAA1267. In an attempt to reduce the broad region of linkage disequilibrium, they genotyped a large number of additional markers. They identified a sub-haplotype of H1 (11% of the population) that contains the association to PD ($p = 0.02$) but it still spanned several loci. Thus, while Tau is known to bind to α -Synuclein and is the most likely gene in the associated haplotype, the genetic data at present cannot rule out other genes in the Tau haplotype as the causative factors.

α -Synuclein: Two meta-analyses in the Caucasian and Japanese populations support the association of a complex microsatellite in the α -synuclein promoter (NACP-Rep1) with susceptibility risk for PD (Mizuta et al., 2002; Mellick et al., 2005). However, other SNPs in the α -synuclein promoter have not been associated with PD (Pastor et al., 2001; Holzmänn et al., 2003).

Parkin: Association studies in the Parkin gene have diverged widely in their conclusions. No meta-analysis has been published so far, but the largest association study did not find any evidence for association with risk for PD (Oliveira et al., 2003). Investigating late-onset PD has been difficult because

many datasets focus on earlier-onset disease phenotypes. However, evidence is mounting that those who are heterozygous for a Parkin mutation within exon 7 of the gene, may be more susceptible to late-onset PD (Oliveira et al., 2003; Foroud et al., 2003). Recent functional protein studies also support this premise. Khan studied 13 unaffected 1st-degree relatives from eight unrelated PD Parkin carriers and found a significant reduction in 18 F-dopa uptake in these heterozygotes relative to controls (Khan et al., 2005). Interestingly, similar data exists that supports the same finding for PINK1 and Gaucher carriers.

Mitochondrial Genome (mtDNA): Mitochondria have their own circular genome. The mitochondrial genome is small (16,000bp) and codes for 26 proteins. Unlike the nuclear genome, it has only one allele, and is not efficient in repairing itself. Mitochondria are inherited primarily from the egg and are quite polymorphic between ethnic groups. Haplotypes in mitochondria are termed haplogroups, and have been very useful in molecular anthropology. van der Walt reported that the J and K haplogroups were associated with decreased risk for PD, particularly in females (609 affected, 340 controls) (van de Walt et al., 2003). Recently, a large study by Pyle of 455 affected, 447 controls supported this finding (Pyle et al., 2005). While van der Walt suggested the causative SNP was the A10398G polymorphism, Pyle et al. felt this was not clear, as the SNP has been found on other haplogroup backgrounds. Another small study looking at A10398G found it trending towards association but was not significant (102 affected, 112 controls) (Otaegui et al., 2004). However, the J haplogroup has been associated with increasing risk for PD in studies in the Irish and Finnish populations (Ross et al., 2001; Autere et al., 2002), but these studies were much smaller in size (90 cases/129 controls and 238 cases/104 controls, respectively).

Inducible NOS (iNOS): Under oxidative stress NOS reacts with superoxide anion to form toxic hydroxyl radicals. Inducible NOS is found in glial cells of the CNS and is induced in response to injury. Levecque and Hague both reported association of iNOS with PD in European and Finnish populations, respectively (Levecque et al., 2003; Hague et al., 2004). Hancock confirmed the association in North Americans, but only in early-onset cases (one member of the family with age-at-onset <40 years) (Hancock et al., 2005). Levecque also found an interaction between smoking and iNOS, which Hancock et al. also recently reported in an even larger dataset. (Hancock et al., 2006).

33.3.2.1.3. Modifier Genes

ApoE has been examined by many groups for association with PD. Several recent meta-analyses concluded that ApoE is associated with risk and age-at-onset for PD, although the effect is not nearly as strong as in AD.

Li demonstrated that GSTO1/2 modifies PD age-at-onset in a manner similar to its effect on AD (Li et al., 2003).

Additionally Oliveira showed that one of the subunits of EIF2B, EIF2B3, located on chromosome 1, has a strong age-at-onset effect in PD (Oliveira et al., 2005). EIF2B is an interesting candidate since mutations in EIF2B are known to cause vanishing white matter disease.

33.3.2.2. *Amyotrophic Lateral Sclerosis (ALS)*

Amyotrophic lateral sclerosis is an inexorably progressive motor neuron disease, in which both the upper motor neurons and the lower motor neurons degenerate leading to muscle atrophy. Patients eventually experience respiratory failure, usually within three to five years from diagnosis. However, the onset of ALS may be subtle and early symptoms are frequently overlooked. As many as 20,000 Americans have ALS, and an estimated 5,000 people in the United States are diagnosed with the disease each year. Onset is usually in the 5th through 7th decade of life.

33.3.2.2.1. Mendelian Genes

Like AD and PD, the majority of ALS cases have no clear familial pattern and appear multifactorial in nature. However, up to ten percent of all ALS cases are inherited as an autosomal dominant disorder. Twenty percent of these familial cases result from a dominant mutation in the superoxide dismutase 1 gene (SOD1) (Jones et al., 1995; Jackson et al., 1997). Superoxide dismutase normally scavenges free radicals. If not neutralized, free radicals act as promiscuous electron donors causing random damage to DNA and proteins. Mouse models carrying the SOD1 mutation undergo motor neuron degeneration analogous to human ALS. However, mice with deleted SOD1 genes do not get ALS. This suggests the SOD1 mutation is a dominant negative that actively causes disease, as opposed to producing disease through haploinsufficiency, where disease results from a deficiency of functional gene products.

33.3.2.2.2. Susceptibility Genes

ApoE: ApolipoproteinE isoforms are the most thoroughly studied ALS candidates. Like AD and PD, ApoE4 appears to have a role in ALS. However, findings for risk and age-at-onset have been inconsistent. The most promising and well supported role for the ApoE4 isoform has been to accelerate disease progression (Al-Chalabi et al., 1996; Moulard et al., 1996).

VEGF: Initial reports favor a role for vascular endothelial growth factor (VEGF) in ALS (Lambrechts et al., 2003). VEGF is an essential cytokine for angiogenesis and vasculogenesis. Additionally, VEGF receptors (VEGFR-2 and NRP1), signaling effectors, and upstream regulators (HIF1A and HIF2A), all remain intriguing candidate genes.

NGF: Neurotrophic growth factors (NGFs) are a group of neuropeptides that play an important role in regulating the growth, differentiation, and survival of neurons in the peripheral and central nervous systems and are therefore reasonable

candidates for a role in ALS. However, there are only few published association studies of NGF-regulating genes in ALS, and one large study failed to support an effect of the ciliary neurotrophic factor (CNTF) locus on ALS risk or clinical phenotype (Al Chalabi et al., 2003). Additionally, mixed results have been reported for the survival motor neuron genes (SMN1 and SMN2) that were originally linked to spinal muscular atrophy.

NF: Abnormal accumulation of intermediate filaments in the perikarya and proximal axons of motor neurons is a common pathological hallmark of ALS. Several studies have examined the neurofilament (NF) subunits and repeating regions, but results are mixed with opposite alleles associated with risk in different studies (Figlewicz et al., 1994; Tomkins et al., 1998; Al Chalabi et al., 1999; Skvortsova et al., 2004).

Glutamate: Glutamatergic excitotoxicity has long been proposed as a mediator of ALS. The glial glutamate transporter EAAT2 is responsible for glutamate removal from motor neurons and suppressed expression of EAAT2 was observed in 60% of patients with sporadic ALS (Rothstein et al., 1995). Abnormal splice variants of EAAT2 have been detected, however, they may not be due to polymorphisms in the EAAT2 gene (Aoki et al., 1998). Similarly, defective RNA editing of the GluR2 subunit of the glutamate AMPA receptor appears to contribute to motor neuron death in sporadic ALS, but there is no clear role for GluR2 alone.

Free Radicals: Oxidative stress appears to play a role in ALS pathogenesis, and studies of genes in the reactive oxidative pathways and reactive nitrogen pathways are ongoing.

Modifiers: In addition to susceptibility genes, modifier genes may play an important role in ALS pathogenesis and may also direct efforts towards effective interventions. For instance, while variants of ApoE and monoamine oxidase B (MAOB) do not appear to increase risk for ALS, ApoE4 appears to accelerate progression and an MAOB allele may delay age-at-onset (Orri et al., 1999). Ongoing work also explores environmental effects on ALS and the role of candidate gene variants in response to specific environmental stressors (i.e., gene x environment interactions).

33.3.2.3. *Progressive Supranuclear Palsy (PSP)*

PSP is the second most common cause of Parkinsonism typified by early gait instability and difficulty with vertical eye movement. PSP is characterized by neurofibrillary tangles composed almost entirely of straight filaments of four repeats of Tau protein. Although most cases of PSP appear to be sporadic, genetic diatheses have been implicated. De Yebenes described a pattern of inheritance consistent with a Mendelian autosomal dominant disorder (De Yebenes et al., 1995). Difficulty recognizing the variable phenotypic expression of PSP may be one reason fewer familial cases have been identified than expected (Rojo et al., 1999). The H1 haplotype of the Tau gene has also been found to have association with increased risk for PSP, as it has been for PD (Conrad et al.,

1997). Recently, the H1 and H2 haplotypes have been shown to be directly associated with a large chromosome inversion involving the Tau gene. (Gijselinck et al, 2006).

33.3.2.4. *Frontotemporal Dementia with Parkinsonism-17*

Frontotemporal dementia (FTD) is characterized by a gradual onset of changes in personality, social behavior, and language. FTD is often associated with parkinsonian symptoms or motor neuron disease. The clinical presentation of FTD is heterogeneous, and FTDs are frequently mistaken for AD or a primary psychiatric disorder. FTD is complex and may present either sporadically or as a familial disorder. In 1994, linkage to chromosome 17 was established in a pedigree with FTD designated disinhibition-dementia-parkinsonism-amyotrophy complex (Lynch et al., 1994). The linkage gave rise to the name frontotemporal dementia with parkinsonism linked to chromosome 17, or FTDP-17. The Tau gene on chromosome 17 was the primary candidate because brains in familial cases of FTD showed neuronal and glial intracytoplasmic Tau inclusions. Since then, more than 25 different mutations, including missense mutations, splice-site mutations, and deletions, have been identified in the Tau gene in more than 50 families with FTD (van Slegtenhorst et al., 2000). Tau mutations can alter Tau splicing, disrupt Tau protein function, or both. However, the frequency of Tau mutations in sporadic cases of FTD, i.e., individuals with no family history of dementia, is rare (Baker et al., 1999). It is important to also realize that a significant number of FTDP-17 patients have not had Tau mutations identified in their families. Very recently these families have been shown to be due to mutations in progranulin, a gene lying near Tau and whose function is not fully understood (Cruts et al., 2006).

33.3.2.5. *Multisystem Atrophy (MSA)*

MSA is generally regarded as a sporadic, late onset (typically 50–65 years) disease whose clinical presentation overlaps with PD. Unlike PD, however, individuals with MSA experience autonomic failure and early cerebellar signs such as ataxia. MSA is characterized by neuronal loss accompanied by oligodendroglial, and α -Synuclein inclusions. No risk factors, either genetic or environmental, have been identified for MSA and familial cases have not been described. Nevertheless, sub-syndromal symptoms of MSA are disproportionately reported by the relatives of patients with MSA compared to controls (Nee et al., 1991). However, a reporting bias among relatives cannot be ruled out. Several studies have looked for polymorphisms in candidate genes, which may predispose an individual towards developing MSA. The apolipoprotein E4 allele is not over-represented in MSA when compared to controls. There are conflicting reports of an association between a cytochrome P-450, CYP2D6 polymorphism, and MSA. Studies have not identified any mutations in the coding regions of the α -Synuclein gene in patients with pathologically confirmed MSA.

33.3.3. Multiple Sclerosis (MS)

Multiple sclerosis is a debilitating autoimmune disorder with a complex genetic component. From the preponderance of evidence, there is compelling support for inherited susceptibility to MS. Consistent with a genetic component to MS, prevalence varies by population, there is familial aggregation of cases, and monozygotic twins (who share all their alleles) consistently have higher concordance rates for MS than dizygotic twins (who share half of their alleles). However, since the concordance rate is less than 100% in monozygotic twins, there appears to be an important environmental component as well, consistent with a multifactorial disease model. The patterns of inheritance have not supported a simple Mendelian model (autosomal dominant, autosomal recessive, or X-linked). However, hidden within the complex inheritance in the majority of cases, Mendelian gene variants could account for a small proportion of disease, as has been described in AD (Pericak-Vance et al., 1995) and PD (Scott et al., 1997). Both candidate gene and linkage approaches have been applied to examine the genetic underpinnings of MS. Candidate genes were chosen from among genes known to have a role in the immune system such as the HLA genes, T-cell receptor genes, and the myelin basic protein gene. One MS susceptibility gene within the major histocompatibility complex (MHC) has been identified and confirmed through linkage and family-based association methods. Allelic association to the HLA-DR2 allele was also confirmed using a family-based association approach (Haines et al., 1998). However, with the exception of the MHC (Bertrams et al., 1972), candidate gene studies have suffered from poor replication of results. Two genomic screens (Sawcer et al., 1996; Haines et al., 1996) have demonstrated suggested linkage to at least three regions in addition to the MHC indicating that further candidate regions should be explored.

Summary

For most of the history of genetic studies, researchers have explored forms of disease that followed the relatively simple rules of Mendelian inheritance. There have been many successes using this strategy, however, the most common disease forms have more complex patterns, and are more challenging to elucidate. Already research has shown us that these common diseases are indeed just clinical phenotypes, in which many different causes lead to a similar clinical presentation. Recognizing this heterogeneity has importance for the development of effective therapies targeted to specific disease etiologies. Additionally, until the genetic heterogeneity is sufficiently characterized, it will be difficult to tease out the environmental contributions to diseases, since different genotypes are likely to respond differently to the same environmental stimuli. At this point in time, identifying and modifying risk based on the known genetic underpinnings of many neurodegenerative

diseases remains problematic. As a result, genetic testing and counseling are reserved primarily for the most well characterized genetic diseases (e.g. early-onset familial Alzheimers disease). Most neurodegenerative diseases have complex etiologies and the benefits of genetic testing remain controversial. However as we advance our understanding of complex genetic interactions, we will finally bring genetics into mainstream medicine and neurology to significantly transform the way we practice medicine.

Review Questions/Problems

1. The majority of the mutations known to cause neurodegenerative diseases in humans have been discovered for

- a. common complex diseases because they affect the most people
- b. diseases with a Mendelian inheritance pattern
- c. multi-system atrophy
- d. non-genetic diseases
- e. diseases with no familial component

2. A characteristic of modern genetic research is

- a. that very few candidate genes are proposed for any given disorder
- b. that positive association studies of candidates have been consistently replicated
- c. all of the above
- d. none of the above

3. In a genetic study, stratification may refer to

- a. unrecognized population sub-types due to recent admixture
- b. unrecognized population sub-types due to incorrect matching of cases and controls
- c. a method for presumably reducing genetic heterogeneity within a sample by narrowly defining the phenotype
- d. all of the above
- e. none of the above

4. Heterogeneity within a disease may manifest as

- a. allelic heterogeneity, in which many variants of a single gene can cause the same disease
- b. locus heterogeneity, in which variants in many different genes may cause the same disease
- c. some of the difficulties underlying genetic studies of neurodegenerative diseases
- d. all of the above
- e. none of the above

5. Penetrance and expressivity refer to

- a. the proportion who get the disease and how the disease manifests respectively
- b. redundant terms
- c. how the disease manifests and the proportion who get the disease respectively

- d. all of the above
- e. none of the above

6. Microsatellites

- a. are relatively highly polymorphic genetic markers
- b. can be amplified by polymerase chain reactions
- c. contain repeated elements
- d. all of the above
- e. none of the above

7. An advantage to using single nucleotide polymorphisms in genetic studies is that

- a. each marker is highly polymorphic
- b. they are common and distributed throughout the genome
- c. they are always within exons, and therefore cause a functional change
- d. all of the above
- e. none of the above

8. Linkage analysis

- a. is limited by its exclusive use of restriction fragment length polymorphisms
- b. utilizes co-inheritance of a region of the genome with the disease locus to which it is "linked"
- c. has the advantage of always identifying causative mutations
- d. all of the above
- e. none of the above

9. Allelic genetic association analyses may find positive associations because the

- a. allele causes the disease
- b. allele is in strong linkage disequilibrium with the disease allele
- c. result is a false positive
- d. all of the above
- e. none of the above

10. Genomic convergence provides

- a. a method for greatly increasing the resolution of linkage peaks
- b. a method for using non-human primates to identify causative alleles
- c. an approach to prioritize candidates for further genetic study
- d. all of the above
- e. none of the above

11. A modifier gene

- a. must cause disease.
- b. alters the expression of a disease.
- c. must be in linkage disequilibrium with the disease allele.
- d. all of the above.
- e. none of the above.

12. Variants of the GSTO gene are associated with

- a. age at onset in AD
- b. age at onset in PD
- c. modifier effects
- d. all of the above
- e. none of the above

13. Causative mutations in which of the following genes has been described in early-onset AD?

- a. amyloid precursor protein, presenilin-1, presenilin-2
- b. presenilin-1, amyloid precursor protein, apolipoprotein C
- c. presenilin-1, presenilin-2, apolipoprotein C
- d. apolipoprotein C, presenilin-2, amyloid precursor protein
- e. huntingtin, presenilin-1, presenilin-2

14. All of the following have been candidates for a role in late-onset AD, but which is the most widely accepted and has the best supporting evidence for increasing susceptibility to AD?

- a. UBQLN1
- b. APOE
- c. GAPD
- d. α -T catenin
- e. VLDL-R

15. Features of the apolipoprotein E-4 allele include

- a. increased susceptibility to late-onset AD.
- b. modification of age-at-onset in AD.
- c. a dose dependent effect on age-at-onset in AD.
- d. an association with other neurodegenerative diseases in addition to AD.
- e. all of the above.

16. Characteristic of FTDP-17 is

- a. a phenotype that may be mistaken for AD
- b. linkage to chromosome 17
- c. abnormal Tau accumulation
- d. all of the above
- e. none of the above

17. Which of the following has been proposed as a candidate for susceptibility to amyotrophic lateral sclerosis?

- a. VEGF
- b. CNTF
- c. glutamate system
- d. all of the above
- e. none of the above

18. The genetics underlying multiple sclerosis are typical for a neurodegenerative disease in that

- a. concordance rates in monozygotic twins is higher than in dizygotic twins.
- b. linkage and association approaches have been used to identify likely candidates for a role in the disease
- c. there is an important environmental component to the disease

- d. all of the above
- e. none of the above

19. Huntington disease is an example of a dominantly inherited disease because

- a. two copies of the disease allele are needed to express the disease
- b. the disease locus is on the X chromosome
- c. only one copy of the disease allele is needed to express the disease
- d. it exhibits classic anticipation
- e. it can only be inherited from an affected mother

20. Huntington disease exhibits all of the following except

- a. autosomal dominant inheritance
- b. anticipation, where the disease may become more severe with an earlier age-at-onset in subsequent generations
- c. it is characterized by expansion of a tri-nucleotide repeat
- d. an autosomal recessive form of the disease
- e. a causative gene has been identified

The Neuroimmune System in Psychiatric Disorders

L. Charles Murrin and Mark P. Thomas

Keywords Alpha-melanocyte stimulating hormone; Adrenocorticotrophic hormone; Corticotropin releasing hormone; Cytokines; Depression; Hypothalamic-pituitary-adrenal axis; Proenkephalin; Proopiomelanocortin; Schizophrenia; Stress response

34.1. Introduction

The earliest evidence for neuroimmune interaction and regulation is the classical immune conditioning experiment of Ader and Cohen in 1975 (Ader, 1987). Since then, it is well established that the central nervous system (CNS) and the immune system interact and regulate one another's function (Blalock, 1989; Madden and Felten, 1995). This interaction can be particularly important at times of extraordinary stress, whether due to psychological factors or to a physical response to an injury or an infection. The CNS regulates immune system function with classical neurotransmitters acting through the central nervous system and peripherally through the sympathetic nervous system; and with neuropeptides also acting through both the central and peripheral nervous systems. The immune system, in turn, alters CNS function, particularly through the release of cytokines. While this reciprocal regulation between the CNS and the immune system is designed to maintain homeostasis, dysfunction in one can lead to aberrant function in the other, producing a pathological state.

Interactions between the immune and nervous system are complex and attempts to decipher these are still incomplete. One of the first empirical findings in support of an interaction between these systems was the discovery of receptors for neurohormones and neuropeptides on cells of the immune system (Hadden et al., 1970; Wybran et al., 1979; Hazum et al., 1979; Landmann et al., 1981). This implied that immune cells can and do respond to the endogenous ligands for these receptors. Conversely, the demonstration of many cytokine receptors and the cytokines themselves in the CNS suggests not only that these small proteins have a functional role in the CNS, but that cytokines released by the immune system may be able

to regulate CNS function (Adler and Rogers, 2005; Cartier et al., 2005). Subsequent studies demonstrated that immune cells also synthesize and release many neurohormones and neuropeptides. This provides a mechanism for local control of the physiological effects of these transmitters, in addition to distant control mediated through the peripheral and central nervous systems. This sharing of ligands and receptors in the nervous and immune systems led to the suggestion that this constituted a complete biochemical information circuit and that this interactive communication system provided the basis for the immune system acting as a sensory system and the brain playing an immunoregulatory role (Blalock, 1994).

In this chapter we will provide an overview of how the hypothalamic-pituitary-adrenal (HPA) axis, the CNS and the immune system are integrated and regulate each other's activity. While there are many neurotransmitters and neurohormones that act directly and indirectly through the CNS on the immune system, such as serotonin, norepinephrine and GABA, we will focus on neuropeptides and cytokines found to regulate the immune response. In particular, we will examine HPA axis regulation of CNS function by release of peptides and glucocorticoids in response to stress and inflammation. We will consider opioid-like peptides as well as CRH and related peptides that are synthesized in the immune system as well as the CNS and how they regulate immune function. We will also discuss cytokines released by the immune system and how they impact CNS function. Finally, we will provide a brief overview of how the neuroimmune system plays a role in psychiatric illnesses such as depression and schizophrenia, a topic explored in more detail in the following two chapters.

34.2. Neurohormones and Their Receptors Associated with Both the Central Nervous System and the Immune System

Most lymphoid tissues are innervated by the sympathetic nervous system, both directly and indirectly. These same tissues express receptors for a variety of hormones, including classical

neurotransmitters and hormones released by tissues at a distance. Lymphocytes, for example, express receptors for steroids, enkephalins, endorphins and catecholamines. Expression of these receptors varies with different immune cell types and within the same cell type at different locations or under different physiological or pathological conditions.

There is considerable evidence for the presence of a subset of monoamine receptors on most components of the immune system and for regulation of these immune cells by the respective monoamine neurotransmitters (Sanders et al., 2001; Madden, 2001). Norepinephrine and epinephrine produce their effects via three separate adrenergic receptors, α -1, α -2 and β (Bylund et al., 1994; Hein and Kobilka, 1997) and all three appear to be involved in regulating immune function. Data supporting a role for β -adrenergic receptors is the most detailed but there clearly is a role for α 1 and α 2 adrenergic receptors as well. Adrenergic regulation of immune system function, through release of norepinephrine and epinephrine from the sympathetic nervous system or from the adrenal medulla, is an important regulatory factor, particularly in times of stress when the adrenergic system is highly active. Acetylcholine produces its effects through activation of both muscarinic and nicotinic cholinergic receptors. Muscarinic receptors, especially the M1 and M3 subtypes, are found on lymphocytes and they appear to be functional, based on studies with muscarinic agonists such as carbachol and oxotremorine. It is not clear whether nor how much nicotinic cholinergic receptors are involved in immune function. Our understanding of the roles of serotonin and dopamine in regulating lymphocyte function also is less developed. Serotonin, which is released peripherally from platelets and the enteric nervous system, probably acts primarily through 5HT1A and 5HT3 receptors. Radioligand binding data also suggest the D2-family of dopamine receptors predominate over the D1-family in the immune system, although regulatory T cells express only D1 and D5 receptors.

A focus of this chapter is the role of neuropeptides in regulation of the immune system. Neuropeptides are distinct from classical neurotransmitters in that they are usually slower acting and their synthetic process is quite different. Most active neuropeptides are synthesized as part of a larger pro-molecule. These peptidic precursors are then processed to produce the smaller, active neuropeptides, sometimes in a cell specific manner. In addition, neuropeptides are generally not metabolized and hence removed from the system as quickly as the monoamines, and so they may have a longer duration of action. We will discuss peptides derived from proenkephalin and proopioidmelanocortin as well as CRH and the related urocortins. Other neuropeptides have also been implicated in regulating immune system function in the periphery and possibly in the CNS, including Substance P and calcitonin-gene related peptide (CGRP). The involvement of peptides in regulating immune and inflammatory reactions has been reviewed (Levite, 2000; McGillis et al., 2001).

34.3. HPA Axis Regulation of CNS Function

The occurrence of physical or psychological events, or "stressors," that threaten the well-being of an organism can lead to activation of a generalized stress response. The stress response consists of a coordinated activation of adaptive processes (collectively referred to as allostasis) that are designed to return the organism to steady-state conditions, that is, homeostasis. This coordinated response is mediated by components of the central nervous system (CNS), the peripheral nervous system (PNS), and the endocrine system. The hypothalamic-pituitary-adrenal (HPA) axis defines the classical core of the neuro-endocrine stress response system. The HPA axis coordinates the component processes of the stress response by serving as the major communication route between the CNS, the PNS and the endocrine system. The HPA axis consists of three major components: the hypothalamic paraventricular nucleus (PVN), corticotrophs in the anterior pituitary gland, and the adrenal cortex. The hypothalamus is situated at the anterior-most end of the brainstem and serves as the final common pathway for regulation of visceromotor and endocrine functions by the CNS. The PVN, situated bilaterally along the midline of the anterior hypothalamus, coordinates endocrine functions via the pituitary gland and visceromotor functions via pathways to the brainstem. The pituitary corticotrophs are one of several distinct cell types in the anterior pituitary, each serving as an interface between the central nervous system and the endocrine system to control some aspect of metabolism or sexual behavior. The adrenal cortex comprises the outer layers of the adrenal gland, which plays a major role in responses to stress, through its innervation by the sympathetic nervous system and via circulating hormones.

The activation of a stress response begins with the appraisal of stressors by the distributed CNS network commonly known as the limbic system. The concept of the limbic system, which was originally defined anatomically, has taken on a functional connotation and now typically refers to CNS systems, which modulate the hypothalamus. These brain areas include the hippocampus, the amygdala, and regions in medial prefrontal cortex. The components of the limbic system all influence hypothalamic output, and constitute a distributed system that regulates affective state and is critically involved in the appraisal and response of the organism to stressors. In general, the hippocampus and the anterior cingulate/prelimbic regions of prefrontal cortex inhibit HPA axis output, while the amygdala and the infralimbic region of prefrontal cortex potentiate HPA axis activity. Thus, different regions of the limbic system modulate the output of the HPA axis in a reciprocal fashion to coordinate the temporal sequence of the stress response, controlling the initiation, propagation, and termination of distinct processes.

34.3.1. Hormones Released by the HPA Axis

Two neuropeptides, corticotrophin-releasing hormone (CRH) and arginine vasopressin (AVP) are released from parvocellular neurons in the hypothalamic PVN to initiate a stress response. The terminal endings of these neurons, located in the median eminence of the hypothalamus, release CRH and AVP into the hypothalamic-hypophyseal portal vessel system, where they travel to the anterior pituitary. The two neuropeptides act synergistically on pituitary corticotrophs to activate the synthesis of pro-opiomelanocortin (POMC). This peptide, discussed in detail below, is processed to produce several peptides including adrenocorticotrophic hormone (ACTH), or corticotropin. ACTH released from corticotrophs travels via the bloodstream to act on cells in the zona fasciculata layer of the adrenal cortex, stimulating the synthesis and release of the glucocorticoids, cortisol (in humans) or corticosterone (in rodents).

In addition to regulating the synthesis and release of ACTH from the pituitary, neurons in the PVN also project to areas in the brainstem that control the output of the sympathetic branch of the PNS. Activation of PVN neurons at the onset of a stress response thus leads to increased sympathetic outflow, resulting in release of norepinephrine from sympathetic nerve terminals and epinephrine from the adrenal medulla. The effects of these catecholamines are responsible for the behavioral syndrome known as the “fight-or-flight” response.

The effects of the neuropeptides and glucocorticoids associated with the HPA axis are mediated through distinct receptor subclasses. Two classes of CRH receptors have been identified, type 1 and type 2, with distinct but overlapping distributions in the CNS (Hsu and Hsueh, 2001; Reyes et al., 2001). It is currently thought that CRH acts through type 1 receptors (CRHR1), while novel ligands have been identified for the related type 2 receptors (CRHR2). These ligands, urocortin II (Reyes et al., 2001) and urocortin III (Lewis et al., 2001), play a role in the regulation of appetitive behaviors and are thought to play a role in the adaptive (slow) phase of the stress response (de Kloet et al., 2005) as discussed below. Expression of mRNA for the urocortins has been demonstrated in the hypothalamus, brainstem, and amygdala (Hsu and Hsueh, 2001). Interestingly, the CNS distributions of the CRHR1 and CRHR2 receptors correspond to the CRH and urocortin terminal fields, respectively.

The effects of the glucocorticoids are also mediated through two distinct subclasses of cytosolic steroid receptors. Glucocorticoid receptors (GRs) are found throughout the brain, but GR density is highest in the hypothalamic PVN, ascending aminergic pathways, and in limbic brain regions (Herman et al., 2003). Mineralocorticoid receptors (MR) are named for their primary ligand, the steroid aldosterone, which is produced by the outer zona glomerulosa layer of the adrenal cortex and regulates sodium balance. However, MRs in the brain have a ten-fold higher affinity for glucocorticoids than GRs and thus respond to lower levels of these hormones during the initial phase of a stress response. MRs are also expressed at high levels

in limbic brain regions; thus there is considerable overlap between these two receptors in key brain areas that regulate the HPA axis.

34.3.2. The Role of HPA Axis in Response to Stress

Under resting conditions, CRH and AVP are released from the hypothalamus in a pulsatile fashion with a frequency of 2–3 episodes per hour (Engler et al., 1989). The amplitude of the neuropeptide pulses normally increases in the morning, resulting in a circadian fluctuation in ACTH and cortisol levels. This daily rhythm is modulated by feeding and activity schedules, but is particularly perturbed by stressful stimuli originating internally (e.g., anxiety or systemic infection) or externally (e.g., threatening situations). Thus, acute stressors lead to activation of the stress response.

34.3.2.1. Modes of the Acute Stress Response

The stress system is characterized by two modes of operation, a fast phase that serves to mobilize and activate, and a slow phase that promotes recovery and adaptation. Each mode is associated with characteristic behavioral changes that are mediated by distinct cellular and molecular mechanisms.

The initial fast phase is manifested behaviorally by increases in vigilance and arousal, and alterations in attention. This phase is associated with the release of CRH and AVP from the hypothalamic PVN, activation of sympathetic outflow and release of catecholamines from the adrenal medulla, and rising blood levels of cortisol. The effects of CRH in the fast phase are mediated through type 1 receptors (CRHR1), which are responsible for activation of the HPA axis and the sympathetic nervous system. Levels of cortisol rise rapidly due to release of ACTH from the pituitary, and serve in the periphery to mobilize metabolic resources and alter immune system responses (discussed below). The effects of cortisol on brain structures, and thus behavior, in the fast phase are mediated primarily by the higher-affinity MRs, which respond to the rising levels of cortisol at the initiation of a stress response. An important aspect of MR-induced changes involves their role in the appraisal of environmental stimuli in this phase of the response. The alterations in neuronal function mediated by the interaction of cortisol with MRs leads to increases in arousal level, heightened vigilance and alertness, and enhancement of attention.

The slow phase of the stress system is characterized by processes that promote recovery from, and adaptation to, the stressful conditions that prompted the response. At the level of the hypothalamus, this phase is probably mediated by the urocortins acting through CRHR2 receptors (Reul and Holsboer, 2002; de Kloet et al., 2005). In contrast to the fast phase, the slow phase is associated with activation of the parasympathetic nervous system, which promotes the appetitive and metabolic functions, which help to restore homeostasis. As cortisol levels

peak and then slowly subside during the slow phase, the lower-affinity GRs are activated and lead to transcriptional changes in target organs that promote recovery. In the brain, GR activation-induced transcriptional changes may be crucial for the consolidation of memory traces involving the association of stressors with sensory stimuli (in the amygdala) (Roosendaal and McGaugh, 1997) and environmental context (in the hippocampus) (Oitzl and de Kloet, 1992).

At all levels of the HPA axis, feedback mechanisms exist that control the output of neuropeptides and circulating hormones. These mechanisms regulate the levels of these factors during normal diurnal cycles, but also act to limit the magnitude of the stress response and terminate its effects. These feedback mechanisms consist of both “short” loops, where each factor acts to inhibit its own secretion, and “long” loops, whereby ACTH acts on PVN neurons to inhibit the secretion of CRH, and cortisol acts on the PVN and the pituitary to inhibit the secretion of CRH and ACTH, respectively (de Kloet et al., 1990; de Kloet, 2003).

34.3.2.2. *Chronic Stress Response*

It is important to distinguish between the response of the HPA axis to acute stressors, and the response to chronic stress. While the HPA response to acute stressors can clearly be seen as an adaptive response that serves to maintain or re-establish homeostasis, the response to chronic stress can lead to maladaptive conditions, especially in “vulnerable” individuals, that may initiate or facilitate CNS disease processes, as discussed below.

34.3.3. *Role of HPA Axis in Inflammation*

The activation of the stress systems affects all tissues of the organism, and the peripheral immune system is no exception. These effects are mediated through at least two pathways: via the HPA axis and by virtue of the innervation of lymphatic tissues by autonomic nerve fibers, especially from the sympathetic nervous system. All lymphoid tissues, primary (bone marrow and thymus) as well as secondary (spleen, lymph nodes, and gut-associated lymphoid tissue) are innervated by sympathetic nerve fibers. As discussed above, most lymphoid cells express catecholamine receptors, including B-lymphocytes, CD4- and CD8-positive T cells, dendritic cells, monocytes, and macrophages.

The HPA axis also directly affects peripheral immune functions via receptors for CRH, ACTH and cortisol.

34.3.4. *Impact of HPA Axis on Psychiatric Disorders*

It is well known that acute and chronic stress can impact certain psychiatric disorders; here we focus on two disorders where the evidence for a role of stress and the activation of the HPA axis is particularly strong. Many lines of evidence suggest that chronic stress is a major risk factor for major depression (MD), and the onset of schizophrenia is often associated with stressful life events.

34.3.4.1. *Major Depression*

The hyper-reactivity of the HPA axis that occurs with chronic stress is also often observed in depressed patients. (Owens and Nemeroff, 1991)

In animal models, intracerebroventricular injection of CRH induces anxiety and a depression-like phenotype (Heinrichs and Koob, 2004), and CRHR1 antagonists decrease the signs and symptoms of depression. In contrast, the urocortins, thought to act via the CRHR2 system and potentially involved in the adaptive phase of the stress response, seem to have anxiolytic properties (Heinrichs and Koob, 2004). The hypercortisolaemia resulting from chronic stress perturbs monoaminergic systems as observed in depression, and causes dysregulation of anxiety and aggressive behavior. Using neuroendocrine tests in longitudinal studies, it has been shown that depressed patients do not respond well to anti-depressant treatment if HPA axis disturbances persist; further, patients showed higher rates of relapse when HPA axis disturbances returned (Zobel et al., 2001). In line with these clinical studies, it is interesting to note that chronic treatment of rats with the anti-depressant amitriptyline resulted in changes in limbic MR and GR that occurred in parallel with HPA axis normalization (Reul et al., 1993). In sum, these observations make a strong case for a major role for the HPA axis in the etiology of depression.

An important aspect of research in depression addresses the role of genetic predispositions and developmental events as causative factors. Based on studies of twins, it is estimated that depression has a heritability of 40% (Sullivan et al., 2000).

34.3.4.2. *Schizophrenia*

While the etiology of schizophrenia is essentially unknown, it is generally accepted that the disease complex is caused by the abnormal development of limbic system structures that are assembled mainly in the third trimester of human gestation (Weinberger, 1987; Waddington, 1993). Additionally, the hypothesis is gaining support that the disease is precipitated by environmental stressors that occur during the period of final maturation of these limbic structures during adolescence. Given the role of the HPA axis in the stress response, it is thus reasonable to hypothesize that alterations in the HPA axis somehow contribute to the etiology of schizophrenia (reviewed in Corcoran et al., 2003). Several versions of a “two hit” model of schizophrenia hypothesize that the disease is produced in individuals who suffer both developmental insults during in utero or perinatal brain development and abnormal responses to environmental stressors during adolescent maturation (see for example Lieberman et al., 1997; Walker and Diforio, 1997; Waddington et al., 1998).

In fact, differences in HPA axis function have been reported in schizophrenic patients. Diurnal measurements of plasma ACTH revealed elevated levels in drug-naïve schizophrenic patients compared to age and sex matched controls, suggesting basal overactivity of the HPA axis (Ryan et al., 2004). It has been proposed that the loss in hippocampal volume (and the

concomitant loss of functional glucocorticoid receptors) demonstrated in schizophrenic patients may contribute to unrestrained and excessive HPA function by decreasing the normal negative feedback control exerted by this structure (Corcoran et al., 2003). In this model, early developmental deficits in hippocampal function would participate in precipitation of schizophrenic symptoms in part by promoting excessive HPA axis responsiveness to stressors. A lack of dexamethasone suppression of cortisol secretion in schizophrenic patients (Sharma et al., 1988; Yeragani, 1990) is consistent with the idea that negative feedback control of the HPA axis is compromised in the disease. However, cause and effect have yet to be determined with confidence. Thus it remains to be determined whether changes in limbic regions that regulate the HPA axis are altered due to chronic stress concomitant with disease onset or whether developmental changes in these structures lead to dysregulation of the HPA axis. Abnormal dendritic structure consistent with glucocorticoid-mediated chronic stress has been reported in schizophrenics in the hippocampus (Rosoklija et al., 2000) and prefrontal cortex (Glantz and Lewis, 2001). It is of course possible that early developmental defects in these structures lead to a positive feedback cycle of dendritic remodeling subsequent to HPA axis dysregulation.

The concept of “stress sensitization”, whereby early life stressors can induce an enhanced reactivity to later environmental adversities (reviewed in Read et al., 2005), may also be relevant to the etiology of schizophrenia. This phenomenon, which results in abnormal activation of the HPA axis, is thought to involve alterations in the mesolimbic dopamine system (reviewed in Laruelle, 2000) resulting in excessive release of dopamine, a hallmark of psychotic episodes (Laruelle et al., 1996). Taken together, it appears likely that prenatal developmental abnormalities in limbic structures that regulate the HPA axis predispose this system to sensitivity to stressors in early childhood and adolescent maturation. This predisposition may then play a key role in the precipitation of psychotic episodes, as well as the deterioration of brain function that accompanies the progression of the disease.

34.4. Neuropeptides as Modulators of the CNS and Immune Function

There is differential expression of neurotransmitter and neurohormonal receptors among the various cell types of the immune system. This suggests that particular neurohormones produce specific and differential effects on immune cells, and hence on immune function. It also suggests that the pharmacology of immune cells will vary from cell type to cell type and that these pharmacological differences represent potential drug treatment strategies in coping with various pathological states. There is still a great deal of work to be done in this field since there is debate in the literature on receptor expression; that is, which cells consistently express which subset of receptors, and whether and how receptor expression is regulated by the changing milieu.

For example, functional activities of β_2 -adrenergic, prostaglandin and histamine receptors are increased in T lymphocytes activated by IL-2 (Dailey et al., 1988). This takes place in an apparently coordinated manner even though the prostaglandin receptors are clearly dominant in regulation of signal transduction in resting cells. The change in functional activity is presumably due to up-regulation of receptor expression. These and other studies indicate that receptor expression is a dynamic aspect of immune system function and it that implies alterations in receptor function are important for immune system activities, in this particular case cellular proliferation.

34.4.1. Peptides Derived from Proenkephalin

Two of the most abundant endogenous opioid peptides, methionine-enkephalin (Met-enk; Tyr-Gly-Gly-Phe-Met) and leucine-enkephalin (Leu-enk; Tyr-Gly-Gly-Phe-Leu) are derived from the precursor protein, proenkephalin (PENK). PENK is a 267 amino acid precursor that contains 6 copies of Met-enk, two of which are extended forms (Tyr-Gly-Gly-Phe-Met-Arg-Phe and Tyr-Gly-Gly-Phe-Met-Arg-Gly-Leu) and one copy of Leu-enk. This ratio is essentially the same as the ratio of these peptides found in brain and adrenal chromaffin cells. The fact that there are two distinct peptides closely related in structure and function proved to be a major obstacle that slowed their discovery (Kosterlitz and Hughes, 1977).

The first two opioid peptides were isolated from pig brain and shown to be active in bioassay systems by Hughes and Kosterlitz in 1975 (Hughes et al., 1975). It was some time later, though, that the precursor proteins for these small peptides were discovered. The first of these to be identified was proopiomelanocortin (POMC). It was not until 1982 that PENK was identified and sequenced in multiple species (Udenfriend and Kilpatrick, 1983).

As mentioned above, PENK contains not only both pentapeptide enkephalins, but also a hepta- and octapeptide enkephalin. This structure is maintained across species (Noda et al., 1982; Comb et al., 1982; Gubler et al., 1982). The processing of PENK into smaller peptides, even for an extended period of time, maintains this assortment of four distinct peptides (Fleminger et al., 1983), indicating that all are active products of PENK and that the longer peptides are not simply alternate precursors for Met-enk. Interestingly, while a great deal of attention has been paid to the role of the pentapeptides, Met-enk and Leu-enk, knowledge of the physiological role of the hepta- and octapeptides is still very limited.

There is evidence PENK is not processed in the same way in all tissues and the suggestion has been made that alternative processing may occur in immune system cells containing PENK, compared to processing in neurons (Eriksson et al., 2001). This would open the possibility that differential processing may lead to release of enkephalin-like peptides from the immune system that would have a different spectrum of activities, at least to some extent, than those derived from neural tissues. This, in turn, would provide the opportunity for differential regulation

of components of the immune system, depending on the source of the enkephalin-like peptide release.

34.4.1.1. Expression of Enkephalins in the Immune System

PENK is distributed widely throughout the brain (Wamsley et al., 1980; Finley et al., 1981; Harlan et al., 1987), indicating involvement of the enkephalins in a variety of physiological functions. The first suggestion that peptides derived from PENK were involved in immune system function came from the work of Wybran (Wybran et al., 1979), which demonstrated specific binding of both Met-enk and morphine to lymphocytes. Early studies also demonstrated that the enkephalins are concentrated in leukocytes compared to other blood components, supporting the idea that immune cells can synthesize the opioid peptides. Since these initial observations, a large body of evidence has provided more detail supporting the idea that the enkephalin peptides are produced by and have important actions in cells of the immune system.

Determination of which PENK products are formed by different immune cells has been difficult because of the lack of antibodies specific to the various peptides. For instance, many studies use readily available antibodies to Met-enk, but the possibility is strong that these antibodies can also react with larger peptides containing Met-enk. In addition, the variations in results reported in the literature are probably due to differences in cell types as well as the inducing signal. For instance, Th2 cytokines, such as IL-4, IL-6 and TGF- β , produce many-fold increases in PENK mRNA in human thymocytes. On the other hand, Th1 cytokines have variable (IL-1 β) or no (IFN- γ) effect (Kavelaars and Heijnen, 2000). Further, Th2 cytokines lead to a 4- to 5-fold increase in Met-enk-like protein in thymocytes, whereas Th1 cytokines produce no such effect. It appears, moreover, that the induced Met-enk itself is not released by thymocytes; rather, larger peptides containing Met-enk are released.

Similar results have been found in T cells. PENK is synthesized in T cells and both synthesized and processed into smaller peptides in macrophages and activated monocytes, but not in unactivated monocytes. Paradoxically, in many cases it has been very difficult to demonstrate release of PENK products. For example, T cells do not appear to secrete detectable levels of PENK-derived peptides whereas monocytes do. On the other hand, under some conditions T cells have been shown to secrete intermediate products of preproenkephalin, the precursor to PENK. These intermediate products appear to inhibit proliferative capacity via unidentified, that is, non-opioid, binding sites. The larger peptides eventually are processed into Met-enk (and Leu-enk) in some cases, whereas in others the larger peptides are probably the active products themselves (Dillen et al., 1993; Hiddinga et al., 1994b).

There are many questions yet to be answered in this area. To compound the problems of determining if the products of PENK are released and are active, the quantity of material provided by the tissues is sometimes small enough to make

consistent quantitative data difficult to obtain. This leads to further confusion and contradictions in the literature.

34.4.1.2. Function of the Enkephalins in the Immune System

Met-enk, the most abundant of the enkephalin peptides, produces effects on its target cells that are both concentration-dependent and modified by the presence of other stimuli. The concentration-dependent effects can be bimodal, with low concentrations producing effects opposite those of high concentrations (Oleson and Johnson, 1988). An example is the differing effects of varying concentrations of enkephalins on the production of reactive oxygen species (ROS) by polymorphonuclear leukocytes. ROS production is enhanced by low enkephalin concentrations and suppressed by high concentrations (Roschetti et al., 1988; Marotti et al., 1992). In a similar manner, Met-enk inhibits antibody production by B cells whereas slightly larger peptides also derived from PENK stimulate B cell antibody production (Hiddinga et al., 1994a; Das et al., 1997). One possible explanation of these paradoxical data is that opioid peptides may play a role as modulators of immune system function, fine tuning the current state of activity, rather than being the primary drivers or determinants of function (Eriksson et al., 2001). As such, the effects of these peptides would be highly dependent on the current status of the immune system, whether activated or inactive, and on which other regulatory factors were present and what their overall effects are. In this sense, the endogenous opioids would act more to maintain homeostasis rather than to specifically activate or inhibit the immune system.

The exact role of Met-enk and related peptides derived from PENK remains controversial since there are many studies with seemingly contradictory results (see Eriksson et al., 2001 for review). Many of these studies were carried out in vitro and how well the results translate to in vivo conditions is not clear at present. In addition, relatively few of these studies used experimental conditions that were the same or even similar to those used in other studies, making comparison and resolution of differences difficult.

34.4.2. Peptides Derived from Proopiomelanocortin (POMC)

Another major source of endogenous opioid peptides as well as non-opioid peptides is proopiomelanocortin (POMC). This large peptide contains the sequences of, and is processed into, a number of smaller peptides, including ACTH, β -endorphin, β -lipotropin, α -MSH, β -MSH and γ -MSH. Which products are derived from POMC depends upon the cell in which the processing takes place. In the anterior lobe of the pituitary POMC is processed into ACTH and β -lipotropin. In the neuro-intermediate lobe the major products are β -endorphin, α -MSH and γ -MSH. POMC was the first of the peptide precursors for which such cell-dependent processing was demonstrated.

34.4.2.1. *Expression of POMC in the Immune System*

The discovery by Blalock and colleagues that POMC was also produced by immune cells was a major event in the developing recognition of interactions between the immune and nervous systems (reviewed in Blalock, 1999). These studies indicated that not only do neurohormones derived from the nervous system alter immune system activity, but also similar or identical hormones can be released from immune cells to regulate the nervous system as well as the immune system itself.

Similar to what was found with the PENK-derived enkephalins, peptides derived from POMC frequently have biphasic dose-response curves; that is, low doses stimulate immune system function whereas high doses usually suppress function. Again, it appears the system is designed to maintain homeostasis in response to a wide range of conditions.

The finding that the immune and neuroendocrine systems both express receptors for opioids and for ACTH and that both systems can synthesize and release peptides active at these receptors, led to the suggestion that the immune system functions as a sensory organ (Blalock, 1984, 1999) and that this forms the basis for the interaction between the two systems. It is well known that the nervous system responds to a variety of stimuli and, when appropriate, releases neurotransmitters and hormones that enable an appropriate reaction to these stimuli or stresses. This can include changes in immune system function. Blalock proposed that the immune system also responds to particular stimuli, in this case environmental changes that would not be readily detected by the nervous system, such as the presence of bacteria or viruses. In response, the immune system releases a variety of compounds, including peptide hormones that will alter both immune and nervous system function.

34.4.2.2. *Beta-Endorphin*

A locally induced inflammation followed by cold-water swimming, a stress that is known to activate intrinsic opioid systems, produces an antinociceptive effect localized to the area of inflammation (Stein et al., 1990a). Through a series of experiments it became apparent that the agent producing this effect was β -endorphin and that it was localized to the area of inflammation; that is, it was not a systemic effect of the peptide. This provided strong evidence that localized release of endogenous opioid peptides in areas of inflammation could play an important role in regulating inflammation and nociception. Subsequent experiments using this same model demonstrated significantly increased levels of both β -endorphin and Met-enk localized to the area of inflammation, although it appeared that β -endorphin was responsible for the antinociceptive effect (Stein et al., 1990b). These studies indicated that localized release of these opioid peptides from immune cells were responsible for the reduction in pain. Further support for the involvement of immune cells in this antinociceptive action came from suppression of the immune system with cyclosporin A, which resulted in the loss of the nociceptive effects of the endogenous opioids. Interestingly, Met-enk did not play an

important role under this experimental paradigm and it was not clear whether Met-enk was released from immune cells, even though it was definitely present in the cells. The paradoxical synthesis of two opioid peptides and the release of only one to produce nociception leaves many unanswered questions, such as why is Met-enk synthesized in the first place? This and many other questions remain.

34.4.2.3. *α -MSH*

The tridecapeptide, α -MSH, is also derived from POMC. While originally discovered through its effects on the skin, α -MSH can alter immune system function. Understanding the role of α -MSH in neuroimmune modulation is still in the early stages (Luger et al., 2003). α -MSH acts through melanocortin-1 receptors (MC-1R), which are expressed by immune cells, including macrophages and monocytes. Both β -MSH and γ -MSH, also products of POMC, act through other melanocortin receptors and these receptors have not been found on immune cells to date. This indicates that α -MSH may be the only of these three to be involved in regulating immune function.

Most studies to date suggest that α -MSH modulates or reduces inflammation, down-regulating proinflammatory cytokines and other proinflammatory molecules (Luger et al., 2003). These effects are produced, at least in part, by inhibition of NF κ B activity. There is some evidence α -MSH may have biphasic effects in this regard since low concentrations increase antibody production by B cells whereas higher concentrations reduce production. Nevertheless, most studies, including recent studies pointing to regulation of IL-8 (Manna et al., 2006), indicate an antiinflammatory role for α -MSH.

As discussed above, several other peptides may be derived from POMC in a cell-specific manner, dependent upon processing within each cell type. The role of ACTH in nervous system-immune system interactions is discussed elsewhere in this chapter. At present a neuroimmune function for the other POMC peptides has not been demonstrated.

34.4.3. *Corticotropin Releasing Hormone*

Corticotropin Releasing Hormone (CRH; corticotropin releasing factor; CRF) plays a major role in CNS regulation of the immune system. In particular, CRH released from the hypothalamus is the first point in HPA axis regulation of immune function. As a critical player in the response to stress, the HPA axis is a primary point of coordination in the neural-immune interaction. This is discussed in Section 34.3 of this chapter. CRH also plays an important role in many CNS functions, including regulation of the autonomic nervous system and endocrine function. CRH is involved in the central response to anxiety and stress, and hence affects immune system function via that route. There is also convincing evidence that CRH can play a role in depression. The central role of CRH has been reviewed (Dunn and Berridge, 1990; Heim and Nemeroff, 1999). Beyond these well-known roles for CRH, this neuropeptide hormone is

also synthesized in immune cells and so appears to play an even more widespread role than originally thought.

Early studies demonstrated a role for CRH in augmenting function of immune cells, such as natural killer cells (Carr et al., 1990). The localization and the synthesis of CRH in the immune system and in immune cells were initially suggested by finding mRNA for CRH in leukocytes (Stephanou et al., 1990) and significant concentrations of CRH in areas of inflammation (Karalis et al., 1991). This suggested CRH was produced locally; that is, in the periphery in areas of inflammation, probably in part by immune cells. Further studies supported these ideas. In Lew/N rats, which are deficient in hypothalamic CRH responses to inflammatory stimuli, there are high levels of CRH in inflamed joints (Crofford et al., 1992). These data suggested that CRH plays the role of an autocrine or paracrine inflammatory factor. The obvious paradox is that CRH plays a powerful antiinflammatory role as the primary CNS activator of the HPA axis, yet in local peripheral sites it has just the opposite effect. Thus, CRH expression and function with respect to inflammation is site specific.

CRH had been shown to have important effects in areas of inflammation, such as augmentation of analgesia by endogenous opioid peptides. It has been further demonstrated that the effects were blocked by local administration of a CRH antagonist, a CRH antibody or by antisense oligonucleotides directed against CRH. This implies that local production and release of this hormone by immune cells do, in fact, occur and are physiologically important (Schafer et al., 1996). It was found that systemic administration of these same various antagonists of CRH action, an approach directed against CRH released from a distant site, was either ineffective or several orders of magnitude less potent than local administration, bolstering this argument.

It proved difficult to definitively demonstrate CRH synthesis from immune cells, although numerous studies provided evidence this does happen (Aird et al., 1993; Ekman et al., 1993). Eventually it became clear that regulation of CRH synthesis and release in immune cells differs from that in hypothalamic neurons. While immune cells may synthesize and release much smaller concentrations of CRH and other neuroimmune peptides, and although their release may require *de novo* synthesis, an inherently slow process, the fact that immune cells release these hormones locally in the target area compensates for both of these factors to some extent. These data indicating site and tissue specific effects of CRH, sometimes even contradictory effects, point to the complex interrelationship between the nervous, endocrine and immune systems, an interaction that has yet to be deciphered completely.

34.4.4. Nociceptin, Endomorphins, and Urocortins

There are several newly discovered peptides that are related to those already discussed above and that appear to have, in varying degrees, a role in neuroimmune function. **Nociceptin, or Orphanin FQ**, is a 17 amino acid peptide that plays a role in pain sensation as well as other complex CNS functions. The

receptor for this peptide, ORL-1, has striking homology with the three classical opioid peptide receptors and so is considered a member of the opioid receptor family, although agonists at ORL-1 are orders of magnitude less potent at the other opioid receptors. The converse is also generally true.

Several studies have shown that ORL-1 are expressed in immune cells, including peripheral blood lymphocytes, T and B cells and polymorphonuclear leukocytes (Halford et al., 1995; Peluso et al., 1998; Hom et al., 1999; Serhan et al., 2001), and these receptors are functionally active (Waits et al., 2004; Halford et al., 1995; Hom et al., 1999; Serhan et al., 2001). Following these findings, nociceptin transcripts were found to be present in peripheral blood lymphocytes (Arjomand et al., 2002). It has been suggested, based on differences in transcripts between immune cells and neurons, that processing of the message and the final form of nociceptin may be cell type specific, similar to other peptides.

The function of nociceptin in the immune system and/or in the interaction between the nervous and immune systems is not clear at present. Studies suggest that it increases T cell activation, suppresses antibody production and is a potent chemoattractant. However, given the presence of both the neuropeptide and its receptor in immune cells, analogous to beta-endorphin and the enkephalins, nociceptin is well positioned to play a role similar to that of the better-known and studied opioid-like peptides.

The **endomorphins** are similar to nociceptin, being endogenous opioid peptides that may play a role in both neural and immune function. Endomorphin-1 and endomorphin-2 are endogenous tetrapeptides that have a very high affinity for mu opioid receptors and are the most selective mu peptide agonists known (Zadina et al., 1997). Originally isolated from brain, the endomorphins have been found in mammalian immune tissues as well. They were first detected in spleen and thymus (Jessop et al., 2000) and subsequently demonstrated in macrophages and lymphocytes (Jessop et al., 2002; Mousa et al., 2002). Expression of both endomorphins is increased in lymph nodes and in areas of inflammation in models of inflammation, but is unchanged in nerve fibers in these models. This, along with a concomitant increase in mu opioid receptor expression and the accumulation of opioid peptide-containing leukocytes in areas of inflammation, suggests the endomorphins play a role in inflammation (Jessop et al., 2002), probably in peripheral control of inflammatory pain (Mousa et al., 2002; Labuz et al., 2006).

The **urocortins** are more recently discovered members of the CRH family (see Reul and Holsboer, 2002; Gysling et al., 2004 for reviews). These three peptides (urocortin, urocortin II, urocortin III) were first isolated from brain. While most of the research involving them has focused on the CNS, it has been shown that the urocortins can alter immune function (Bamberger and Bamberger, 2000; Baigent, 2001; Theoharides et al., 2004). There also have been demonstrations of urocortin expression in immune cells (Bamberger et al., 1998; Bamberger and Bamberger, 2000; Baker et al., 2003), providing a parallel with other neuropeptides discussed above. While the physiological and

pathological functions of the urocortins is largely unknown at present, the similarity between the structure, receptors and localization within the immune system for CRH and the urocortins strongly suggests a coordinating or balancing role for this family of peptides in regulation of the immune system.

34.5. Cytokines as Regulators of the CNS and Immune Function

34.5.1. Cytokine Actions in the CNS

Cytokines are peptide factors that are classically associated with humoral communication between immune system elements. However, it has become clear that many members of this large family of molecules also play diverse roles within the nervous system. Cytokine-mediated communication between neural elements has been implicated in all aspects of nervous system development, including cell proliferation, migration, differentiation, and programmed cell death. Further, in the adult brain cytokines play vital roles in the cellular and synaptic plasticity that is requisite for learning and memory processes. During brain injury, cytokines coordinate the response of neuroimmune elements including astrocytes and microglial cells, the brain-resident monocyte-derived phagocytes.

In addition to their role in coordinating immune system functions, cytokines mediate communication between the peripheral immune system and the central and peripheral nervous system (Plata-Salaman, 1991). During an innate immune response, cytokines released by macrophages, vascular endothelial cells, and other cells activate the HPA axis, resulting in the release of adrenal glucocorticoids (Silverman et al., 2005).

In addition to activation of the HPA axis, the pro-inflammatory cytokines also influence behavior; the outcome of this influence is manifested as a syndrome known as “sickness” behavior. This syndrome is characterized by a number of behavioral responses including anhedonia (inability to experience pleasure), decreased general activity and exploratory behavior, decreased feeding and sexual activity, and increased sleep (Dantzer, 2001, 2004; Larson and Dunn, 2001).

34.5.2. Cytokines and the HPA Axis

It has become clear that cytokines are potent activators of the central stress response, serving as the afferent limb of the response system during acute or chronic inflammatory stress. Several pro-inflammatory cytokines, including tumor necrosis factor- α (TNF- α), interleukin-1 β (IL-1 β), and interleukin-6 (IL-6), can activate the HPA axis (Chrousos, 1995; Tsigos et al., 1997).

34.5.2.1. Interleukin-1 β

The cytokine IL-1 β serves a central role in the initiation and coordination of inflammatory responses, both in the periphery and in the CNS. Neurons, astrocytes, microglia, and epithelial cells in the brain constitutively express this cytokine, and its central effects in regulating central inflammatory responses

are well-documented (Basu et al., 2004). However, IL-1 β released by peripheral immune cells can also affect the CNS; in fact this cytokine is believed to play a major part in eliciting the sickness behavioral syndrome mentioned above. Thus, in animal models, peripheral administration of IL-1 β causes such diverse responses as decreased exploratory behavior and locomotor activity, decreased operant responding to rewards, anorexia, inhibition of sexual behavior, promotion of sleep, and anxiety reactions. IL-1 β also increases fever through actions on the hypothalamus. Thus, human and animal data support the idea that IL-1 β is a key regulator of behavioral responses to peripheral immune system activation (Basu et al., 2004).

34.5.3. Impact of Immune System Cytokines in Psychiatric Disorders

The growing awareness of the role of cytokines in regulating CNS function has resulted in a great deal of research in the last decade on their potential role in psychiatric disorders. Initially driven by studies of “sickness” behavior, evidence has accumulated suggesting that levels of pro-inflammatory cytokines are altered during the course of several psychiatric disorders.

34.5.3.1. Role in Major Depression

A large number of studies have demonstrated increases in several pro-inflammatory cytokines in patients diagnosed with MD. It is interesting to note that all of these cytokines are associated with activation of the HPA axis. Thus, elevations in IL-6 have been consistently associated with clinically diagnosed depression (Sluzewska et al., 1995; Maes et al., 1997; Lanquillon et al., 2000; Musselman et al., 2001; Alesci et al., 2005). The circadian pattern of IL-6 secretion is shifted 180 degrees out of phase in depressed patients (Alesci et al., 2005), and IL-6 levels are significantly correlated with severity of depression (Musselman et al., 2001). Prior to administration of antidepressant medication, levels of IL-6 were elevated in patients who did not respond to the treatment, whereas responders showed normal levels before treatment, suggesting that IL-6 levels could be used to predict treatment outcome (Lanquillon et al., 2000). Depression has also been associated with increases in IL-1 β (Owen et al., 2001; Thomas et al., 2005) and TNF- α (Hestad et al., 2003; Tuglu et al., 2003). These studies support a role for pro-inflammatory cytokines in MD, and suggest that targeting pro-inflammatory cytokines and their signaling pathways may represent a novel strategy for treatment of the disease (Raison et al., 2006).

34.5.3.2. Role in Schizophrenia

As mentioned above (Section 34.3.4.2) there is growing evidence supporting the hypothesis that schizophrenia is caused by a combination of genetic or epigenetic factors that affect limbic brain structures in the last trimester of development and stress-induced environmental influences during the final maturation of these structures late in human adolescence. This “two hit” idea has led to research directed at two potential targets for cytokine action: the effects of cytokines on the

development of the nervous system, and the acute effects of cytokine administration in generating psychotic symptoms.

While the etiology of schizophrenia is essentially unknown, it is generally accepted that the disease complex is caused by the abnormal development of limbic system structures that are assembled mainly in the third trimester of human gestation (Weinberger, 1987; Waddington, 1993). Additionally, the hypothesis is gaining support that the disease is precipitated by environmental stressors around the period of final maturation of these limbic structures. This "two hit" idea has led to research directed at two potential targets for cytokine action: the effects of cytokines on the development of the nervous system, and the acute effects of cytokine administration in generating psychotic symptoms.

A number of environmental factors have been correlated with the development of schizophrenia including birth trauma, maternal viral infection, and season of birth (reviewed in Nawa et al., 2000). Prolonged labor results in abnormally elevated serum IL-6 levels (De Jongh et al., 1997), suggesting a possible link between immune system activation and the perinatal complications associated with the development of schizophrenia. Given the role of proinflammatory cytokines in repair of tissue damage and infection, it is interesting that TGF- α and IL-1- β can suppress the normal expression of brain-derived neurotrophic factor (BDNF), a neurotrophin that is a key regulator of neuronal and synaptic development, in the hippocampus (Lapchak et al., 1993). Conversely, IL-1- β causes up-regulation of nerve growth factor (NGF), another factor that regulates growth and development of central neurons, in microglial cells (Heese et al., 1998). These findings compel further research into the interactions between cytokines and the brain-derived trophic factors that may lead to abnormal development of brain regions that ultimately result in the manifestation of schizophrenia in the mature brain.

Several reports of persistent psychosis following the administration of interferon- α (Tamam et al., 2003; Thome and Knopf, 2003; Telio et al., 2006) or high doses of IL-2 (Denicoff et al., 1987) demonstrate that cytokines could conceivably mediate some aspects of cognitive impairment observed in schizophrenic patients. These studies are interesting in light of the fact that evidence for abnormal levels of cytokines in schizophrenic patients is accumulating (Malek-Ahmadi, 1996; Prolo and Licinio, 1999). However, further studies are needed to show a causative relationship between cytokine levels in patients and the precipitation of psychotic episodes.

34.6. Overview of the Role of the Neuroimmune System in Depression and Schizophrenia

There has been a long-standing interest in the relationship between psychological disorders and the status of the immune system, based upon the everyday observation that people with

significant psychiatric problems also appear to have a high incidence of other physical ailments. Conversely, people suffering from infectious or inflammatory disease appear to have a greater incidence of CNS problems. Two chapters in this book cover this topic extensively. Therefore, only a brief overview is provided here.

34.6.1. Depression and the Immune System

In recent years there has been increased investigation of potential links between immune function and depression. Two large meta-analyses of multiple studies found that patients with major depression show reliable changes in immune function (Herbert and Cohen, 1993; Irwin, 1999), including lowered proliferative response of lymphocytes to mitogens, lower NK cell activity and changes in white blood cell populations. Data suggest that major depressive disorder (MDD) can alter immune function and this is most likely to occur in patients with severe depression (Herbert and Cohen, 1993; Irwin, 1999; Maes, 1999; Frank et al., 2002). While the initial thought was that immune function was depressed in MDD, more recent evidence has suggested that many aspects of the immune system are likely to be activated. Both stress and major depression, two disorders that share many features, can be characterized by activation of some immune capacities and suppression of others (Raison and Miller, 2001).

The mechanisms for these interactions are not well defined, although numerous hypotheses have been advanced. It should be noted at the outset that attempts to determine the relationship between depression and altered immune function are confounded by the multiplicity of factors known to be associated with both and that may alter the interrelationship. Examples include age, gender, sleep status, the likelihood that depression represents a complex of disease states with varying involvement of the immune system, and the frequent presence of other psychiatric or physical disorders which can affect both psychological status and immune function. A detailed review of this topic has been published (Irwin, 2001). Indeed, it has been pointed out by Irwin that current data suggest immune changes in MDD specifically correlated with the disorder are also seen with stress and other psychiatric disorders, suggesting some common characteristic(s) shared by these problems (Irwin, 2001).

In addition, the likelihood that depression represents a complex of disease states with varying involvement of the immune system supports the idea that there is a subgroup of depressed patients who have associated alterations in immune function. Indeed, data suggest that different types of depression display distinct, and even opposite, changes in neuroimmune functions (Antonijevic, 2006). As a result of multiple issues, there are contradictory, or at least inconsistent, findings in the literature. This is characteristic of most types of studies of depression, again probably because depression represents multiple disease states.

There is increasing evidence that aberrations in immune system function induce or at least support the development of

MDD. Activation of some aspects of the immune system is generally associated with MDD, even in patients who are otherwise quite healthy. Many studies support this idea (Raison et al., 2006). Proinflammatory cytokines, such as IL-6 and TNF- α , are increased in plasma and in the CNS. There also are increases in the level of chemokines and adhesion molecules.

Several studies have shown increased plasma levels of IL-6 in patients with MDD. In a more extensive study, Alesci and colleagues found that IL-6 levels were increased in MDD patients throughout the circadian cycle (Alesci et al., 2005). There was a 12-hour shift in the circadian rhythm of IL-6 plasma levels and its complexity was reduced. Even though IL-6 is a known activator of the HPA axis, cortisol levels were not consistently changed in MDD patients compared to controls. Additionally, it was found that IL-6 levels, with their altered rhythm, correlated significantly with mood ratings. IL-6 also induces a “sickness” behavior very similar to depression. These data suggest a direct relationship between IL-6 and depression.

A related example is the effects of interferon- α (IFN- α) on mood and, specifically, its ability to produce significant depression (Trask et al., 2000; Raison et al., 2006). IFN- α is used to treat several serious disorders, including malignant melanoma and hepatitis C. A major side effect of prolonged or high dose therapy with this agent is major depression, even to the point, though rare, of suicidality. Estimates are that this occurs in as many as 30–50% of patients undergoing IFN- α treatment. A history of psychiatric symptoms is considered a relative contraindication to the use of IFN- α , and a psychiatrist should closely monitor treatment of such patients using this drug. Further indications that the syndrome produced by IFN- α is depression are that it is responsive to treatment with antidepressants and that there are indications of changes in serotonin and possibly norepinephrine metabolism centrally. Alterations in both of these neurotransmitters are associated with depression. It is also interesting that IFN- α is a potent inducer of IL-6, which may be associated with the induction of depression.

As indicated by this brief overview there is considerable evidence for a close relationship between changes in the immune system and depression, particularly MDD. Whether there is a clear cause and effect relationship between these is not known in most cases, although there are strong data in the case of IL-6 and IFN- α , as noted. It will be important to determine more clearly the exact relationship between depression and immune system alterations. There is also a need to determine which of the immune alterations that are found are clinically important (Irwin, 2001).

34.6.2. Schizophrenia and the Immune System

The involvement of the immune system in schizophrenia is an even more complicated issue compared to involvement with depression. There have been suggestions for many decades that schizophrenia is associated with immune dysfunction (Vaughan et al., 1949). However, it is only recently that substantial evidence relating to this idea has begun to appear and this is even less

definitive than data supporting a link between the immune system and depression. Analogous to depression, there are multiple problems with dissecting a role for the immune system in schizophrenia, including the multiplicity of the disease etiology and the difficulty in controlling for the many factors that are frequently associated with schizophrenia and that also alter immune function themselves. These include age, gender, sleep status, the likelihood that schizophrenia represents a complex of disease states, and the frequent presence of other psychiatric or physical disorders which can affect both psychological status and immune function. The difficulties with such studies have been set forth by Rapaport and Muller (2001).

Nevertheless, despite the difficulties, there are intriguing findings that have strengthened the hypothesis that neuro-immune interactions are altered in schizophrenia patients. One argument for an association between immune function and schizophrenia is that epidemiological data show a linkage between prenatal viral infections and subsequent appearance of schizophrenia. There have also been studies that show an acute exacerbation of schizophrenia can occur in response to immune system dysfunction. These have been reviewed (Rapaport and Muller, 2001). The most extensively examined idea is that schizophrenia is associated with autoimmune diseases or that schizophrenia may, in certain instances, be associated with a lack of normal autoimmune function (Gaughran, 2002; Jones et al., 2005; Kipnis et al., 2006).

Autoimmune diseases are associated with some schizophrenia-like symptoms. There are also associations between the appearance of several autoimmune diseases and schizophrenia, although these are both positive and negative correlations. It has been proposed that there is a genetic linkage between schizophrenia and autoimmune diseases. Again, there are both positive and negative associations. Many of these correlations have been refuted by later data. The extensive literature documenting multiple changes in immune system markers and function in the schizophrenic population has been reviewed extensively (Gaughran, 2002).

An interesting hypothesis advanced recently is that schizophrenia is, at least in some cases, due to loss of a specific aspect of autoimmunity due to prenatal loss of a specific subset of T cells (Kipnis et al., 2006). This idea is based on a series of studies from the Schwartz lab that indicate autoimmune T cells in the CNS play a fundamental physiological role, exerting a protective effect on neurons when they are subjected to stress. The hypothesis is that there is a prenatal loss of the relevant autoimmune clones so that when stress appears later in life, the neuro-protective effects are lost or at least diminished, and ultimately neurodegeneration occurs, leading to schizophrenia. This idea is consistent with a number of characteristics of schizophrenia. The dopamine hypothesis posits abnormally high levels of dopamine in schizophrenia. Dopamine release is increased centrally in response to stress and this normally suppresses regulatory T cells, leading to increased activity in protective autoimmune T cells. In schizophrenia, however, there is a loss of autoimmune protection, consistent with a lack of protective

autoimmune T cells. This would result in lack of neuroprotection and greater neurodegeneration. It is generally accepted that schizophrenia is a developmental disorder. There are also considerable data indicating schizophrenia is often associated with maternal inflammation or viral infection. Both of these could lead to loss of immune cells prenatally, perhaps to a specific loss of protective autoimmune clones. There is a great deal of work to be done to prove or disprove this hypothesis, but it does bring together several aspects of schizophrenia and it provides a framework for investigating a potential role of autoimmunity in schizophrenia.

Summary

The studies reviewed in this chapter demonstrate that a strong and reciprocal relationship exists between the central nervous system and the immune system. Indeed, the term “neuroimmune system” is clearly justified and appropriate to emphasize the fact that nervous and lymphoid tissues constitute a unified system that functions in the maintenance of homeostasis. The conventional division between the two systems has blurred, as well as the distinction between neuropeptides on the one hand, and immune cytokines on the other. Two lines of research have altered our perspective on neuroimmune interactions: (a) the identification of conventional neuropeptides and their receptors, especially those related to the HPA axis, in most lymphoid tissues, and (b) the large body of evidence that cytokines, historically associated with immune system communication, play vital roles in nervous function.

The role of the HPA axis in coordinating responses to stressors, and the role of the immune system in mediating the “sickness” response, underscore this reciprocal relationship between the CNS and the immune system. However, the relationship is complex, and it should be clear that we are in the early stages of understanding how immune tissue can contribute to psychiatric disorders. In spite of this nascent state of knowledge, the evidence for hyper-reactivity of the HPA axis and the alterations in cytokine levels observed in both MDD and schizophrenia serve as a foundation for further research establishing a causative relationship between alterations in immune system function and these debilitating CNS disorders.

Review Questions/Problems

- Name three of the four peptides for which proenkephalin is the precursor.**
- The major physiological role of the enkephalins in regulating immune function appears to be**
 - stimulation of all immune cells
 - inhibition of all immune cells
 - maintenance of homeostasis
 - increased expression of regulatory T cells
 - decreasing reactive oxygen species production
- Name the three products derived from proopiomelanocortin (POMC) for which evidence is the strongest supporting involvement in regulating immune system function.**
- The site of action for α -MSH is**
 - mu opioid receptors
 - melanocortin-1 receptors
 - glucocorticoid receptors
 - melatonin receptors
 - ACTH receptors
- Local release by immune cells of which neuropeptide plays the most important role in nociception produced in areas of inflammation by the immune system?**
 - methionine-enkephalin.
 - α -MSH
 - ACTH
 - β -endorphin
 - urocortin-1
- Which neuropeptide is antiinflammatory when activating the HPA axis but is proinflammatory when released locally by immune cells?**
 - ACTH
 - CRH
 - β -endorphin
 - nociceptin
 - γ -MSH
- Endomorphins are endogenous neuropeptides with a very high affinity and selectivity for**
 - mu opioid receptors
 - glucocorticoid receptors
 - melanocortin-1 receptors
 - ORL-1 receptors
 - beta adrenergic receptors
- Which cytokine has been found to induce major depressive disorder in a high percentage of patients when used to treat malignant melanoma or hepatitis C?**
 - IL-6
 - TNF- α
 - IL-4
 - interferon- α
 - IL-10
- The neuropeptide synthesized and released from the CNS, particularly the hypothalamus, as well as from immune cells is**
 - ACTH
 - urocortin-1
 - CRH
 - TNF- α
 - insulin

10. The proinflammatory cytokine found to have increased levels in plasma and CNS in major depressive illness and whose levels correlate significantly with mood rating is

- a. IL-6
- b. TNF- α
- c. CRH
- d. IL-2
- e. β -endorphin

Major Depression, Bipolar Syndromes, and Schizophrenia

Frederick Petty, Sriram Ramaswamy, Prasad R. Padala, Jean D. Deupree, and David B. Bylund

Keywords Major depressive disorder; Biopolar disorder; Schizophrenia; Mood disorders; Biogenic amine hypothesis; Learned helplessness; Antidepressant drugs; Mood stabilizers; Dopamine hypothesis; Antipsychotic drugs

35.1. Introduction

Psychiatry is a medical subspecialty dealing with mental and behavioral disorders. Mental illness refers to diseases of the brain, because the mind is a function of the brain, and illness is a synonym for disease. Psychiatric illnesses are generally differentiated from neurological illnesses in that neurological disorders tend to have demonstrable anatomical or physiological abnormalities associated with them. Although the biological basis of psychiatric disorders is well established, the neurochemical and neuroanatomical abnormalities associated with these disorders tend to be subtle. Recent advances in brain imaging and molecular genetics provide optimism regarding our ability to understand psychiatric illnesses on a more biological and molecular basis. However, at this time, psychiatric diagnoses remain clinical and descriptive. That is to say, they are based on observation regarding symptoms, complications, and outcome. The basis of psychiatric diagnosis continues to be the psychiatric interview and mental status examination. At this time, there are no laboratory or imaging tests to diagnose mental illnesses, though laboratory tests may be helpful in diagnosing medical conditions with psychiatric symptoms, such as thyroid disease.

The major or most severe psychiatric disorders include depressive disorders, bipolar disorder (manic-depressive illness), and schizophrenia. Depression and bipolar disorder are classified as mood disorders, because the predominant feature of these conditions is an inappropriate or abnormal emotional state. Schizophrenia, on the other hand, is classified as a thought disorder, because the predominant symptoms involve disturbances in perception and thinking.

Mood disorders and schizophrenia are different from other psychiatric disorders in that they may be associated with

psychotic features, including hallucinations and delusions. Also, mood disorders and schizophrenia tend to be more disabling and associated with greater degrees of personal and social impairment.

Other psychiatric disorders, which are not discussed in detail in this review, include anxiety disorders, personality disorders, somatoform disorders, eating disorders, and substance use disorders.

35.2. Major Depressive Disorder

35.2.1. Clinical Diagnosis and Description

Major Depressive Disorder is characterized by a persistent low mood and decreased interest and pleasure. Although feeling depressed as a reaction to unfortunate life events, such as the death of a loved one, is normal, persons with major depressive disorder have a low mood and decreased interest and pleasure which are out of proportion to the environmental stress. Further major depressive disorder persists for a prolonged period of time, long after a “normal” depressive reaction, such as bereavement would have resolved. Additionally, persons suffering depression have a cluster of physical and psychological symptoms, including sleep and appetite disturbance, low energy, and psychomotor retardation (i.e., observably slowed mental and physical processes). Psychological symptoms of depression include feeling worthless, helpless, hopeless and guilty, and difficulty thinking and concentrating. In severe cases, persons with depression may feel that life is not worth living, and develop suicidal thoughts upon which they may act. Further, for a diagnosis of major depressive disorder, these symptoms need to persist for at least two weeks, though usually they are present for much longer before coming to medical attention.

Although, technically, the pathognomonic symptoms of major depressive disorder are low mood and decreased interest or pleasure (anhedonia), from a clinical perspective, the associated symptoms are often those that cause a person

to request medical examination. Typically, someone with depression requests help from a primary care provider for complaints of insomnia, fatigue, memory problems, vague aches and pains, and weight loss (Alarcon et al., 1998). The physical and laboratory examination is usually negative, and the patient may resist a psychiatric explanation for these symptoms. Fortunately, there is increased awareness, both in the general public, and in the medical profession, of depressive disorders as treatable medical illnesses. Nevertheless, epidemiological studies suggest most patients with major depressive disorder do not receive any treatment, let alone adequate treatment (Shapiro et al., 1984).

35.2.2. Diagnostic Criteria

The diagnostic criteria for Major Depressive Disorder (American Psychiatric Association, 2000) are:

1. Sustained low or depressed mood
2. Decreased interest or pleasure
3. Sleep disturbance, decreased or increased
4. Appetite disturbance, weight loss or gain
5. Problems with memory and concentration
6. Feeling worthless or guilty
7. Psychomotor agitation or retardation
8. Fatigue or loss of energy
9. Thoughts of death, suicidal ideation

For the diagnosis of major depressive disorder, a person must have either symptom 1 or 2, plus five out of nine symptoms, and these symptoms must occur most of the day, nearly every day, for at least two weeks. Major depressive disorder is differentiated from other depressive disorders, including minor depression (dysthymia), recurrent brief depression, and adjustment disorder with depressed mood.

Most authorities who have studied major depressive disorder over the last century have concluded that major depressive disorder may be subdivided into two types. These two types have been referred to by variable nomenclature: "psychotic" vs. "neurotic"; "endogenous" vs. "reactive"; "with melancholic features" vs. "without melancholic features"; or "primary" vs. "secondary" (Robins and Guze, 1972). This classification refers in part to severity, and in part to distinct symptoms. There continues to be debate regarding the utility of this classification, though some data suggest that the more severe depressions should receive first line treatment with pharmacological interventions or electroconvulsive shock therapy. The less severe cases may respond as well to psychological treatments, such as cognitive-behavioral psychotherapy.

35.2.3. Epidemiology

The lifetime population prevalence for major depressive disorder in the United States is 5–12% for men, and 10–25% for women (Eaton et al., 1989; Blazer et al., 1998). Part of this discrepancy may result from the methods used in the surveys. Large-scale

population surveys using highly structured interviews performed by lay interviewers tend to result in higher prevalence, whereas more focused studies using trained mental health professionals tend to result in lower estimates. Nevertheless, major depressive disorder is one of the most common medical conditions, with a prevalence comparable to diabetes and cardiovascular disease. The health care burden of major depressive disorder is comparable to that of cardiovascular diseases, and is estimated, on a worldwide basis to be among the top three in total expense.

Major depressive disorder has similar prevalence rates in various ethnic, racial, and cultural groups. Some studies have suggested variability of prevalence in some countries, but more transnational and transcultural research is needed.

Epidemiological studies are consistent in finding higher rates of major depression in women than in men, with the usual ratio about 2:1 (Kessler et al., 1993). Also, higher rates of major depressive disorder are found in single or divorced persons, compared to married persons; in urban settings, compared to rural settings, and in young rather than middle aged or elderly persons. The female gender prevalence in major depressive disorder is only found during the years of reproductive potential (Kessler et al., 1993). Prior to menarche, boys have higher rates of depression than girls, and after menopause, men have comparable rates to women. This suggests that hormonal or physiological factors associated with the female menstrual cycle may contribute susceptibility to developing major depressive disorder, though psychosocial factors cannot be altogether excluded.

The age at risk for major depressive disorder is virtually life long. The highest incidence (new cases) is during a person's twenties and thirties. However, the first episode of depression may occur in childhood or adolescence, and in old age. Interestingly, during the last 50–100 years, the age of onset has decreased, with higher rates of major depression seen in young persons, and an increase in childhood and adolescent depression (Klerman and Weissman, 1989). Several factors have been considered in attempting to interpret this historical trend. One factor might be increased sophistication in ascertainment of cases. Another factor is the "period effect" where psychosocial stressors during a particular period might place individuals at greater risk. Also considered is the "cohort effect" in which risk of illness varies between different generations. This effect may be sensitive to genetic influences. Finally, "age effects" are considered, in which risk of illness varies during specific times of the life cycle. Needless to say, these effects probably interact. Nevertheless, it is notable and remarkable that the age of onset of first episode of major depressive disorder was around 40–50 three generations ago, and is now 20–30.

35.2.4. Course of Illness

Major depressive disorder is a recurrent, episodic illness. Untreated episodes of major depressive disorder last, on the average for 6 to 18 months. In 10–20% of cases, however, the major depressive disorder becomes a chronic condition,

which may persist for years. About 70% or more of persons who have one episode go on to develop another, and a pattern of recurrent illness, with numerous episodes, is seen in perhaps half of cases (Keller et al., 1992).

Complications of major depression are significant. Persons with major depressive disorder have higher rates of physical illness (Katon and Sullivan, 1990). They are also more likely to develop substance use disorders, particularly alcohol abuse and dependence (Sullivan et al., 2005). Persons with major depressive disorder experience considerable social, vocational, and family impairment, due, in part, to problems with memory, concentration, and poor judgment.

The worst complication of major depressive disorder, of course, is suicide. Persons with major depressive disorder have a lifetime risk of suicide of about 15% (Guze and Robins, 1970). This highlights the fact that major depressive disorder is a potentially lethal illness. Also, this represents one of the major sources of preventable death.

35.2.5. Etiology

Major depressive disorder is familial, with higher prevalence seen in first-degree family members of affected individuals than in the general population (Winokur and Pitts, 1965). This suggests that major depressive disorder may be genetic, and the most compelling evidence that it comes from studies of twins. In these studies, one twin has major depressive disorder, and rates of concordance for the illness are compared between monozygotic twins and dizygotic twins. Monozygotic twins share identical genes, while dizygotic twins are like siblings, sharing half of their genes. Both monozygotic and dizygotic twins are assumed to share similar environmental and familial influences. In major depressive disorder, monozygotic twins are about 40% concordant for the illness, while dizygotic twins are about 10% concordant. For dizygotic twins, the prevalence is comparable to that found in siblings (McGuffin et al., 1991). To date, the precise genetic cause of major depressive disorder remains elusive. It is, like diabetes, a complex genetic disorder, likely involving several genes, and does not follow simple Mendelian genetics.

In addition to genetics, other factors play a role in the etiology of major depressive disorder, or monozygotic twins would be 100% concordant for the illness. Identifying these factors presents a challenge, particularly because many are difficult to measure in a quantitative manner. Childhood abuse and neglect are considered risk factors, as is early parental death or separation (Pine and Cohen, 2002). Stressful life events are also considered to be risk factors (Paykel, 2003). The contribution of life stress to the development of depression is minor, however, because most people who experience even severe stressful life events do not develop major depression. Among the most stressful life events are the death of a spouse or child. Persons who suffer this experience develop a full-blown major depressive disorder (as opposed to grief reaction or bereavement) only about 10–30% of the time. Other stressful life events include

catastrophic major medical conditions, such as a myocardial infarction or cancer. Again, a major depression in response to these events is seen in only about 25% of cases. Further, many people develop severe, disabling depressive disorders in the absence of any perceptible life stress.

Of stressful life events, those which are unpleasant or represent loss, and over which the person has no control, are more likely to lead to major depression, according to the learned helplessness model. In this model, inescapable and unpleasant stress leads to the belief that one's response cannot influence outcomes, hence "learned helplessness" (Seligman 1972). This is considered a depressive cognitive attribution, and changing these negative thought patterns is the basis for cognitive psychotherapy.

An interaction between genetic and environmental causes is considered most likely to be causal in many cases. Evidence for this is provided by the recent report that persons who inherit the short allele of the serotonin reuptake site are more likely to develop major depression after several severe stressful life events (Caspi et al., 2003), though this finding has not been widely replicated.

Other psychiatric illnesses, particularly the anxiety disorder, are also risk factors for development of major depressive disorder. Persons with anxiety disorders (panic disorder, obsessive compulsive disorder, social phobia, generalized anxiety disorder, and posttraumatic stress disorder) go on to develop major depressive disorder over the course of 5–20 years in over 50% of cases.

In summary, the etiology of major depressive disorder suggests a genetic component, environmental influences, and other, as yet undetermined factors.

35.2.6. Neurobiology

35.2.6.1. Biogenic Amine Hypothesis

This hypothesis was first formulated around 1965, and encompasses both a catecholamine hypothesis and a serotonin hypothesis. The essential features of the hypothesis involve the idea that decreased levels or activity of norepinephrine and/or serotonin is responsible for the development of the symptoms of depression, and that pharmacological treatments exert their therapeutic effects by restoring biogenic amine function (Schildkraut, 1967). This hypothesis originated from a clinical observation that patients treated with reserpine (the first effective specific antihypertensive agent) often developed symptoms of major depressive disorder. Reserpine was found to deplete biogenic amines. Subsequently, the first pharmacological treatments for depressive disorders, namely monoamine oxidase inhibitors and tricyclic antidepressants, were found to increase biogenic amine levels in brain.

Most of the evidence supporting the biogenic amine hypothesis is indirect. Specifically, deficits of norepinephrine and/or serotonin have been difficult to demonstrate. Considerable research into urinary levels of methoxy-hydroxy-phenylethanolamine glycol (MHPG), a norepinephrine metabolite, in depressed

patients yielded inconsistent results, probably because this metabolite is not a reflection of central noradrenergic activity as once thought (Eisenhofer et al., 2004). Levels of the serotonin metabolite, 5-hydroxyindole acetic acid (5-HIAA) were reported to be low in cerebrospinal fluid of patients with depression (Asberg et al., 1984). However, subsequent research suggests that this reflected impulsive aggressive behavior and suicidality more than the depressive syndrome.

Another test for the biogenic amine hypothesis would involve precursor loading strategies. In other words, compounds which could increase brain levels of norepinephrine and/or serotonin should demonstrate antidepressant efficacy. Results of these studies have been mixed. Several positive findings were reported with treating depression with the serotonin precursors tryptophan and 5-hydroxy tryptophan (5-HT) (Shaw et al., 2001), but these were not consistently replicated. Less positive results were reported with attempts to increase brain norepinephrine levels with precursors.

Possibly the best evidence suggesting involvement of norepinephrine and serotonin in major depressive disorder devolved from depletion studies (Delgado et al., 1990). In these studies, patients who have responded to treatment for depression are given procedures, which deplete brain levels of serotonin or norepinephrine. Serotonin levels are decreased by use of a low monoamine diet, followed by a drink which includes all the amino acids except the serotonin precursor tryptophan. Norepinephrine levels are depleted by administration of alpha-methylparatyrosine. In patients who had responded to treatment with a serotonergic antidepressant, depletion of serotonin caused a prompt and dramatic, but brief reoccurrence of the symptoms of major depression. In patients who had responded to treatment with a noradrenergic antidepressant, depletion of norepinephrine caused a relapse into depression. The converse was not true; in other words, serotonin depletion did not cause relapse in patients who responded to noradrenergic antidepressants, and vice versa.

In addition to the biogenic amines, the amino acid neurotransmitters are also implicated in the neurochemistry of major depressive disorder. Neurotransmitter γ -aminobutyric acid (GABA) levels are low in brain, cerebrospinal fluid, and blood of patients with major depressive disorder (Petty, 1995; Brambilla et al., 2003).

35.2.6.2. Neurotransmitter Receptor Alterations

Changes in adrenergic receptors in the brains of patients diagnosed with major depression have been documented and used to support the biogenic amine hypothesis, although the studies have not been entirely consistent. The density of the alpha-2 adrenergic receptor is generally found to be increased, at least when an agonist radioligand is used in the binding assay (Ordway et al., 2003). Alpha-2 adrenergic receptors are also up-regulated in animal models of depression (Flügge et al., 2003).

One of the most consistent findings in preclinical studies of antidepressant treatments (including electroconvulsive shock)

is the downregulation (as measured by radioligand binding) of beta-adrenergic receptors. This decrease in receptor density is likely secondary to the increased concentration of norepinephrine in the synaptic cleft. Other alterations in the G protein signaling cascade have been documented, including alterations in G protein and adenylyl cyclase (Donati and Rasenick, 2003; Millan, 2004). Another hypothesis, that decreased neurogenesis might be the cause of depression, is supported by the effects of stress on neurogenesis and the demonstration that neurogenesis seems to be necessary for antidepressant action (Thomas and Peterson, 2003; Henn and Vollmayr, 2004). However, no inclusive hypothesis concerning a mechanism of action of antidepressant therapies has been forthcoming.

35.2.6.3. Neuroendocrine Findings

Perhaps the best established and most widely replicated finding in biological psychiatry is that patients with major depressive disorder have elevated levels of the stress hormone cortisol (Carroll et al., 1976). The original finding involved measuring blood levels of cortisol in depressed patients, and these were consistently higher than control over a 24 h day, even allowing for the circadian variation in cortisol levels. Subsequently, the dexamethasone suppression test was used to further test endocrinological abnormalities in patients with major depressive disorder (Carroll, 1985). In this test, the high potency synthetic steroid hormone dexamethasone is administered at 11 pm. In normal controls, levels of cortisol at 8 am are significantly reduced. In about half of patients with major depressive disorder, cortisol levels are not suppressed by dexamethasone. Non-suppression in the dexamethasone suppression test was not found to be specific for depressive disorders, with significant degrees of non-suppression found in other psychiatric syndromes. Further evidence for dysregulation of the hypothalamic-pituitary-adrenal axis in major depressive disorder was provided by studies of corticotrophic releasing hormone. Levels of this hormone, which regulates peripheral cortisol, were elevated in cerebrospinal fluid of patients with major depressive disorder. Whether the hypercortisolemia associated with major depression represents a risk factor or a consequence of illness remains unclear. Certainly, having major depressive disorder, with its attendant physical, psychological, and social stressors, is in and of itself a highly stressful experience. Abnormalities in cortisol function may be a consequence of the illness, rather than a risk factor, because dexamethasone suppression reverts to normal upon recovery from illness. Nevertheless, this line of research has resulted in attempts to study cortisol antagonists as antidepressant agents.

In addition to abnormalities in the cortisol system, abnormal function of growth hormone and of thyroid hormone and of their regulatory mechanisms has been reported. Again, these findings are not specific to depression (Schatzberg et al., 2002).

35.2.6.4. *Neurophysiological Correlates*

Patients with major depressive disorder are reported to have decreased latency to first episode of rapid eye movement (REM) sleep (Kupfer and Foster, 1972). This finding may relate to the hypothesized dysregulation in circadian rhythms found in mood disorders. This interest in circadian rhythms has lead to development of some specific treatments for depression, including sleep deprivation and light therapy.

35.2.6.5. *Brain Imaging*

Numerous studies of brain function in major depression have been undertaken. Studies using positron emission tomography generally show decreased metabolism in the frontal lobes of depressed individuals, more so on the left (Bench et al., 1992). This abnormality is not specific to depression, being observed in other psychiatric conditions such as bipolar disorder and obsessive compulsive disorder. The abnormalities reverse with successful treatment.

35.2.7. *Animal Models*

Several animal models of depressive disorders have been studied, and space does not permit detailed review of these findings. Animal models of depression have fallen into three general categories: Stress induced, “ethologically relevant,” and genetic (Machado-Vieira et al., 2004). Of the stress-induced models, learned helplessness, chronic mild stress, and forced swim (behavioral despair) are best characterized (Willner and Mitchell, 2002).

In the learned helpless model, animals (usually rats) are subjected to a brief (1–2h) inescapable shock. Subsequently, they are tested in a task in which they can terminate the shock by an operant response. Animals with prior inescapable shock exposure do not perform as well in the test (Maier and Watkins, 2005). Advantages of the learned helplessness model include its use in studies of neurochemical changes, and that it responds to repeated, rather than acute, antidepressant drug administration. Disadvantages of the model include its dependence on acute stress administration, suggesting it may better model posttraumatic stress disorder than major depressive disorder.

The chronic mild stress model involves subjecting rats or mice to unpredictable “mild” stressors over the course of 2–4 weeks. These stressors include soiled bedding, changing light-dark cycle, food deprivation, noise, strange cage mates, and tilted cages. Consumption of a sweet solution is generally decreased in these stressed animals, and this is returned to normal consumption by chronic administration of antidepressant drugs. This decreased response to rewards is thought to model anhedonia or loss of pleasure in depressive disorders. Advantages of the model include its relationship to chronic stress, which may be more relevant to major depressive disorder than acute stress. Disadvantages of the model include its being very labor and time intensive, in addition to difficulties in replication (Willner, 2005).

The forced swim test involves subjecting animals (rats or mice) to a brief (15 min) swim in a restricted space, followed by a test the next day in a similar water tank. Animals will characteristically assume a passive, immobile posture on the second day of the procedure. This is interpreted as representing “behavioral despair,” thought to be an analogue of depressive behavior. Administration of antidepressant drugs between the first and second swim leads to decreased immobility in the test (Cryan et al., 2005a). A variant of this model is the tail suspension test in mice (Cryan et al., 2005b). Advantages of the model include its wide spread replicability, ease of use, and ability to predict antidepressant drug efficacy. Disadvantages include the fact that the model responds to acute antidepressant drug treatment, unlike human depression.

The ethologically relevant models include the resident intruder and social hierarchy paradigms (Mitchell and Redfern, 2005). These models are relatively recent, and have the relative advantage of relying on more naturalistic stressor, compared to shock or swim. Also, they respond to chronic, but not acute antidepressant drug administration.

Genetic models hold great promise, particularly in light of the evidence that major depressive disorder has a prominent genetic component. The best studied genetic model is the Flinders Sensitive Line, which was originally bred for increased responsiveness to cholinergic agonists (Overstreet et al., 2005). Several lines of neurochemical and pharmacological evidence support the validity of this model. Another genetic model is congenital learned helplessness, in which rats are bred for susceptibility to shock induced helplessness (King et al., 1993; Henn and Vollmayr, 2005). Interestingly, after several generations, rats no longer require inescapable shock stress to exhibit helpless behavior. More research is needed on the pharmacology of this model.

Other models include the olfactory bulbectomy model (Song and Leonard, 2005). Lesions of the olfactory bulb cause behavioral changes, interpreted to result from disturbed function of the limbic system. These behaviors are reversed by chronic antidepressant administration.

In summary, many animal models of depressive disorders have been developed, each with relative advantages and disadvantages (Nestler et al., 2002). The validity of these models for human depressive disorders continues to be the subject of debate. Probably, this reflects the lack of comprehensive data on the molecular pathophysiology, genetic etiology, and relation to stress in human major depressive disorder.

35.2.8. *Treatment*

The treatment of major depressive disorder includes both pharmacological and psychological interventions. As to psychological treatments, cognitive and behavioral techniques have demonstrated positive results. Patients who respond to psychological intervention are usually in the range of mild to moderate symptom severity.

Pharmacological treatment for depression involves use of antidepressant drugs. Drugs are available that act by a variety of mechanisms to increase biogenic amines in the nerve endings including: inhibiting monoamine oxidase, an enzyme involved in the metabolism of biogenic amines; and inhibiting the norepinephrine transporter (NET) and/or serotonin transporter (SERT) responsible for the reuptake of biogenic amines into the synapse (Table 35.1). The net effect is to increase levels of the biogenic amines in the synaptic cleft (Table 35.1). In addition to blocking the transporters the action of some drugs is thought to be due to a direct action on biogenic amine receptors. Most of these agents are selective for either the norepinephrine or the serotonin transporters thus resulting in the buildup of norepinephrine and/or serotonin in the synaptic cleft. Some have activity at the dopamine transporter (DAT) (Tables 35.1 and 35.2).

However, these neurochemical effects are acute. That is to say, biogenic amine reuptake is blocked within minutes of drug administration. The therapeutic effects, on the other hand, in ameliorating or reversing the symptoms of major depression, require repeated antidepressant drug administration. Though some improvement in symptoms is often noted during the

first week or two of treatment, the full effects of the medication require 4–8 weeks to become manifested. This delayed onset of therapeutic drug action is generally thought to reflect a change in biogenic amine receptor density or sensitivity which requires time to develop, such as down regulation of the beta-adrenergic receptor. However, it remains a clinical challenge and experimental puzzle.

Interestingly, in the learned helplessness animal model of depression, reversal of helpless behavior may be obtained acutely by direct intracerebral drug administration into frontal cortex, though reversal of helpless behavior by systemic drug administration requires several days (Sherman and Petty, 1980). This suggests that the reversal of depressive symptoms by antidepressant drugs may involve pharmacokinetic as well as pharmacodynamic effects (Petty et al., 1982).

The antidepressant drugs are hardly panaceas. Only about 50–60% of patients experience a response to the medications, where “response” is arbitrarily defined as 50% or greater reduction in symptoms (Hirschfeld, 1999). This compares with a 30–40% response to placebo. Rates for remission, with complete recovery and absence of symptoms, are even lower, in the 20–30% range. No one antidepressant is more

TABLE 35.1. Selective antidepressants classified according to their drug class.

Drug class	Drugs	Amine effects
Norepinephrine/Serotonin reuptake inhibitors		
Tertiary amine tricyclics	Amitriptyline	NE, 5-HT
	Clomipramine	NE, 5-HT
	Doxepin	NE, 5-HT
	Imipramine	NE, 5-HT
	Trimipramine	NE, 5-HT
Secondary amine tricyclics	Amoxapine	NE, DA
	Desipramine	NE
	Maprotiline	NE
	Nortriptyline	NE
	Protriptyline	NE
	Reboxetine	NE
Selective norepinephrine reuptake inhibitor (SNRI)		
Selective serotonin reuptake inhibitors (SSRI)	Citalopram	5-HT
	Fluoxetine	5-HT
	Fluvoxamine	5-HT
	Paroxetine	5-HT
	Sertraline	5-HT
	Venlafaxine	5-HT, NE
Atypical antidepressants	Atomoxetine	NE
	Bupropion	DA, NE?
	Duloxetine	NE, 5-HT
	Mirtazapine	5-HT, NE
	Nefazodone	5-HT
	Trazodone	5-HT
Monamine oxidase (MAO) inhibitors	Phenelzine	NE, 5-HT, DA
	Tranylcypromine	NE, 5-HT, DA
	Selegiline	NE, 5-HT?, DA?
	Moclobemide	NE, 5-HT, DA

TABLE 35.2. Selectivity of selective antidepressants for NET. The antidepressants are listed according to the selectivity for the NET over SERT or DAT.

Drug	NET ^a	SERT ^a	DAT ^a
NET-selective drugs			
Oxaprotiline	+++	–	–
Maprotiline	++	–	–
Mianserin	++	–	–
Desipramine	+++	+	–
Atomoxetine	+++	++	–
Reboxetine	+++	++	–
Nortriptyline	+++	++	–
Amoxapine	++	++	–
Doxepin	++	++	–
SERT-selective drugs			
Bupropion	–	–	+
Amitriptyline	++	+++	–
Milnacipran	++	+++	–
Imipramine	++	+++	–
Trazodone	–	+	–
Venlafaxine	+	+++	–
Clomipramine	++	++++	–
Fluoxetine	+	++++	–
Paroxetine	++	++++	+
Fluvoxamine	–	+++	–
Sertraline	+	++++	++
S-Citalopram	–	++++	–

^aThe symbols represent the relative affinities (Frazer 1997; Owens et al., 1997; Tatsumi et al., 1997; and Leonard and Richelson, 2000) of the drugs for the NET, SERT, and DAT with (++++), representing drugs with Ki values <1 nM, (+++) Ki from 1 to 10 nM, (++) Ki from 10 to 100 nM, (+) for Ki from 100 to 1000 nM, and (–) for drugs with affinities >1000 nM.

effective than another, and it is not unusual for patients to receive a sequence of several medications, or combinations of medications, before they recover.

In addition to antidepressant drugs, some forms of psychological treatments have been shown effective for treatment of major depressive disorder. These include cognitive behavioral psychotherapy and interpersonal psychotherapy (Weissman, 1979). These therapies differ from traditional psychoanalytically oriented methods in that the therapist takes an active role, the patient is expected to do “homework,” and the treatment is time limited, usually for about six months. Little data are available regarding whether the combination of medications and psychotherapy is more effective than either treatment alone, but data are suggestive of an additive effect.

Electroconvulsive therapy is usually reserved for severe or treatment resistant cases of depression, though the response rates to this treatment are higher than for drugs.

35.2.9. Immunological Correlates

This topic is covered in depth in another chapter. However, briefly, therapy with interferon has been shown to induce many symptoms of depression, including fatigue, depressed mood, psychomotor retardation, social withdrawal, and impaired

memory and concentration. This may be due to dysregulation of the hypothalamic-pituitary-adrenal axis and stress response systems, and disturbance of serotonin function. Administration of proinflammatory compounds in animal models leads to “sickness” behavior, with correlates to depressive behavior. Long term administration of antidepressant drugs may attenuate this behavior, and inhibit the production of proinflammatory cytokines. The depressive syndrome associated with interferon therapy is responsive to serotonergic antidepressants (Schiepers et al., 2005).

35.3. Bipolar Disorder

35.3.1. Clinical Diagnosis and Description

Persons with bipolar disorder experience episodes of mania or hypomania. These episodes are characterized by hyperactivity, decreased need for sleep, increase in goal directed activity, excessive and rapid speech, starting many new projects, increased engagement in high-risk behavior, and a euphoric or irritable mood. Lack of insight is a hallmark of mania. A person in the manic phase of the illness may impulsively go on spending sprees, gamble, engage in promiscuous high-risk sexual behavior, become violent, and develop bizarre behavior. Although family and friends will recognize these behaviors as maladaptive, if not dangerous, the manic person will be oblivious to the consequences of his or her actions, and often justify them with rationales that may seem plausible. Persons who are experiencing episodes of mania often demonstrate psychotic thoughts; such as feeling they have supernatural powers, or feeling paranoia.

Additionally, persons with bipolar disorder may experience episodes of depression similar to major depressive disorders. Bipolar disorder was previously referred to as “manic-depressive” illness, reflecting the existence of both manic and depressive episodes. Also, some patients with bipolar disorder have mixed episodes, with both manic and depressive symptoms concurrent.

Though most persons who do not have bipolar disorder may consider the manic episodes to be beneficial and a positive experience, given the increased energy and euphoric mood, many patients with bipolar disorder find manic episodes to be very unpleasant, characterized by high levels of irritability and anxiety. Bipolar disorder, like major depressive disorder, is an episodic, recurrent condition, and in between episodes, the bipolar person may have function and behavior that appear completely normal.

35.3.2. Diagnostic Criteria

The diagnostic criteria for the depressive episodes in bipolar disorder are similar to those for major depressive disorder. The diagnostic criteria for a manic episode (American Psychiatric Association, 2000) are:

1. A distinct period of elevated, expansive, or irritable mood
2. Grandiosity or increased self-esteem
3. Decreased need for sleep
4. Pressured speech, more talkative than usual
5. Racing thoughts, or flight of ideas (jumping from one thought to another)
6. Distractibility, attention easily drawn to irrelevant stimuli
7. Increased goal directed activity, psychomotor agitation
8. Excessive involvement in pleasurable activities that have high potential for unpleasant consequences (spending sprees, sexual indiscretion)

For a diagnosis of mania, a person must have symptom 1, as well as three or more of symptoms 2–8. If the mood in symptom 1 is only irritable, then four or more of the other symptoms are required. Further, the symptoms must persist for at least a week or lead to hospitalization for the diagnosis of mania to be made. Additionally, the symptoms must cause marked impairment in occupational or social function. Also, the symptoms cannot be due to a medical condition or to a substance use disorder. Manic episodes share many features with amphetamine use disorder.

About half of patients with bipolar disorder experience what are referred to as hypomanic, rather than manic, episodes. Hypomanic episodes are differentiated from manic episodes by being briefer, in that only four days of symptoms are required, and by not having psychotic symptoms, nor marked impairment in functioning, nor requiring hospitalization.

Persons who experience manic episodes are classified as having Bipolar I Disorder, while those who experience only hypomanic episodes are classified as having Bipolar II Disorder.

Technically, having one or more depressive episodes is not required for a diagnosis of bipolar disorder. In other words, a person with bipolar disorder may only experience manic or hypomanic episodes and be classified as bipolar. Practically speaking, virtually all bipolar patients experience depressive episodes at some point during the course of illness.

35.3.3. Epidemiology

The lifetime population prevalence of Bipolar I disorder in the United States is about 1% (Kessler et al., 1994). There is no gender prevalence, with women as likely as men to develop the illness. The prevalence of bipolar I disorder does not appear to be influenced by race, ethnicity, or geography. Similar prevalence rates are reported in most countries, although large scale cross national and cross-cultural studies are needed. The prevalence of bipolar II disorder is less well understood, but is estimated to be about 3–5% (Berk and Dodd, 2005). Needless to say, patients with bipolar II disorder may be less likely to come to medical attention.

The usual age at onset of bipolar disorder is from the late teens into the twenties. The first onset of a manic episode rarely occurs after age 40. In fact, if a person experiences what appears to be the first manic episode after age 50, a medical or substance induced cause is likely (Burke and Wengel, 2003).

35.3.4. Course of Illness

Bipolar disorder is an episodic illness, with an individually variable course. There is no characteristic course that defines most patients. Some individuals may experience few manic episodes, but suffer recurrent depression. Others may have frequent, severe manic episodes, with brief and infrequent depressive episodes. Not infrequently, recurrent depression precedes the development of mania or hypomania. The average length of a manic episode, untreated, is about 3 months. Depressive episodes in bipolar disorder are usually of 3–6 month duration.

Between 10% and 15% of persons with bipolar disorder develop rapid cycling, defined as having four or more episodes per year (Akiskal, 2000). Often patients with rapid cycling will demonstrate marked seasonality with their episodes, such as developing mania in the Spring and Fall, and depression in the Summer and Winter.

There has been some speculation that bipolar disorder worsens with age, with episodes becoming more frequent and severe in middle age. However, there are very few data that support this theory.

Some evidence supports the idea that a manic or hypomanic episode may be induced in vulnerable patients by antidepressant medications (Goldberg and Truman, 2003). This phenomenon, known as the “switch” effect, has been clinically observed in many cases. Some data suggest that treatment with antidepressants, particularly those with dual action at both norepinephrine and serotonin, may precipitate a manic episode in bipolar patients (Stoner et al., 1999; Shulman et al., 2001; Yuksel et al., 2004). Though widely accepted from a clinical perspective, this phenomenon is still somewhat controversial from a research perspective.

35.3.5. Etiology

Bipolar disorder is largely genetic in etiology. Concordance in monozygotic twins is about 70%, which is probably the highest of all psychiatric disorders. Interestingly, the most prevalent psychiatric disorder in first-degree relatives of persons with bipolar disorder is major depressive disorder, suggesting a possible overlapping genetic vulnerability for both mood disorders (Kelsoe, 2000).

The precise mechanism for mode of transmission of bipolar disorder has been the focus of extensive research. To date, the results are not conclusive. Some reports of linkage to chromosome 11 were initially promising, but not replicated. Other reports of linkage to the X chromosome had initial positive findings but difficulty in replication. The strongest data are for linkage to chromosome 18, with several replications of the initial finding (Kelsoe, 2000). A major challenge in genetic studies in bipolar disorder in particular, and of psychiatric illnesses in general, revolves around the heterogeneity of the clinical conditions. These disorders are clinically described, and the diagnosis often involves subjective symptoms and interpretation of behavior. At this time, there are no objective laboratory findings for linkage to genetic studies. “Bipolar

disorder” may well include a number of different and distinct biological subtypes. For example, persons who have recurrent brief depression, with occasional mania or hypomania, and a strong family history of major depressive disorder, probably have a different illness than those with recurrent, severe mania and a strong family history of bipolar disorder, and infrequent depression.

Nevertheless, this is an area of intensive research, with the potential for improved diagnosis and treatment. The best estimates are that several genes are involved (5–15). The environmental influence in bipolar disorder is less than that for major depressive disorder. Some risk factors have been identified, including negative stressful life events.

35.3.6. Neurobiology

The neurobiology of bipolar disorder is less well studied than that of major depressive disorder. Early studies of monoamine metabolites found that they were increased in patients with bipolar disorder, but these were subsequently interpreted as due to the increased motor activity seen in these patients.

The “kindling” model of bipolar disorder has attracted considerable interest. This model originally developed after the clinical observation that anticonvulsant drugs were effective for the treatment of bipolar disorder, particularly in the manic phase of the illness. Rodent research on epileptic seizures demonstrated that decreasing electrical stimuli were needed over time to generate seizures, hence the term “kindling.” Some clinical evidence suggests, that in some patients with bipolar disorder, the illness progresses, such that in the earlier phases it is more likely to occur in response to stress, while in the later stages, episodes are autonomous and independent of stress. Hence the hypothesis was developed that the reoccurrence of episodes in bipolar disorder might represent a “kindling” phenomenon (Post et al., 1992). The kindling hypothesis has stimulated interest (Ghaemi et al., 1999) but has yet to lead to breakthroughs in understanding the neurobiology of bipolar disorder.

More recent research has focused on examining underlying commonalities in the biochemical actions of the mood stabilizers used to treat bipolar disorder (Zhou et al., 2005), in studies of postmortem brain tissue (Post et al., 2003), and in signal transduction pathways and regulation of gene expression (Bezchlibnyk and Young, 2002). For example, altered levels or function of G-protein alpha subunits and protein kinase A and C have been found in bipolar patients, as well as disruption in second messenger cascades such as the ERK/MAPK pathways.

35.3.7. Animal Models

Developing an animal model of bipolar disorder is challenging, due to the dramatically different clinical presentations of mania and depression. Animal models of depression are described above, and can be considered to model the depres-

sive phase of bipolar disorder. Animal models of mania have included techniques to increase motor activity, such as administration of stimulants, increasing dopamine activity, sleep deprivation, and brain lesions (Machado-Vieira et al., 2004). These models are responsive to medications used to treat bipolar disorder to varying extents.

Recently a hyperactivity model induced by a combination of D-amphetamine and chlordiazepoxide was studied. Lamotrigine, valproate, and carbamazepine, all used to treat bipolar disorder, were all found to decrease this hyperactivity (Arban et al., 2005). Interestingly, while most mania models assume an increase in dopamine, an early model used dopamine depletion with intracerebroventricular injection of 6-hydroxydopamine, which induces hyper-reactivity to environmental stimuli, but not hyperactivity per se (Petty and Sherman, 1981). This model was responsive to chronic lithium and to chronic electroconvulsive shock, and also to acute chlorpromazine, while imipramine worsened the behavior.

Development of an animal model for bipolar disorder probably awaits a better understanding of the genetics of this illness. Development of such a model is further complicated by the fact that clinically some patients respond to lithium, but not valproate, and vice versa.

35.3.8. Treatment

The treatment of bipolar disorder is complex, and depends on the particular phase of illness. The “mood stabilizers” form the foundation of treatment. These include lithium and the anticonvulsant drugs, valproate, and carbamazepine (Bowden, 1998; McElroy and Keck, 2000; Post, 2000). Recently, lamotrigine has been found effective in some patients (Post, 2000). The goal of treatment with mood stabilizers is reduction of frequency and severity of episodes of depression and mania.

When patients present in a manic episode, rapid remission of symptoms is required, particularly if the person is psychotic or experiencing severely disruptive behavior. In these cases, use of an antipsychotic medication is usual. These medications may include use of conventional or “first generation” antipsychotic medications, such as chlorpromazine or haloperidol (Table 35.3). Recently, the “second generation” or “atypical” antipsychotics have also shown efficacy in treatment of acute mania (American Psychiatric Association, 2000). The latter agents are preferred due to their lower likelihood of inducing neuro-

TABLE 35.3. Antipsychotic medications (examples).

Typical	Atypical
Chlorpromazine	Aripiprazole
Haloperidol	Clozapine
Perphenazine	Olanzapine
Thiothixene	Quetiapine
Trifluoperazine	Risperidone
	Ziprasidone

logical side effects. Atypical antipsychotics include clozapine, risperidone, olanzapine, ziprasidone, quetiapine, and aripiprazole, all of which have demonstrated antimanic efficacy.

When bipolar patients present in a depressive episode, initial treatment with a mood stabilizer is recommended (Post, 2000). If a depressed bipolar does not respond to treatment with a mood stabilizer, an antidepressant is prescribed. Most patients with bipolar disorder end up on multiple medications. Electroconvulsive therapy is an effective treatment for bipolar disorder in both the manic and depressed phases of the illness.

35.3.9. Immunological Correlates

Relatively little research has examined the immunological factors in bipolar disorder. Plasma levels of IFN-gamma/TGF-beta 1 and IL-4/TGF-beta 1 were reported to be higher in symptomatic manic patients than controls in one study (Kim et al., 2004). More research is needed to elucidate this relationship.

35.4. Schizophrenia

35.4.1. Clinical Diagnosis and Description

Schizophrenia is a chronic and disabling mental illness, characterized by the presence of psychotic symptoms, including hallucinations and delusions. Hallucinations are sensory misperceptions, in which a person will experience an auditory, visual, or other sensory experience in the absence of an observable stimulus. Thus, persons experiencing a hallucination will, for example, hear voices speaking when there are no persons near by, or see things that other persons do not see. Persons with schizophrenia usually have auditory hallucinations, but may also have hallucinations in other sensory modalities.

Delusions are defined as fixed false beliefs. For example, persons who experience paranoid delusions may believe that they are under surveillance. In some cases this may assume bizarre proportions, such as the belief that aliens from outer space are not only observing, but also controlling the person's actions. Delusions are impervious to a rational explanation. Persons who have delusions will continue in their belief regardless of plausible evidence that their beliefs are wrong.

Persons with schizophrenia also frequently display disorders in the form of their thinking. This may be manifest by difficulty maintaining a systematic train of thought in conversation, and is referred to as "loose associations." Persons with schizophrenia may respond to a question with an answer that is not logical, or change subjects during a conversation in manners that are difficult to follow.

In addition to having hallucinations and/or delusions ("positive symptoms") persons with schizophrenia also have prominent "negative symptoms." These include amotivation, alogia (less speech), and affective flattening (poor emotional response to stimuli).

Generally, schizophrenia leads to severe occupational and social maladjustment. Persons with schizophrenia exhibit

"downward drift" in that they have difficulty establishing and maintaining normal social, educational, and occupational activities, considering their background and expectations. Many, if not most, persons suffering from schizophrenia are unable to maintain gainful employment and social interactions.

35.4.2. Diagnostic Criteria

For a diagnosis of schizophrenia (American Psychiatric Association, 2000), a person must have at least two of the following:

1. Delusions
2. Hallucinations
3. Disorganized speech
4. Disorganized behavior
5. Negative symptoms

If the delusions are bizarre, or the hallucinations consist of voices keeping a running commentary on the person's behavior or thought, only one symptom is required. Further, the symptoms have to persist for at least six months, and be accompanied by significant impairment in social or vocational impairment, or impairment in self care. Also, the symptoms must not be due to drug abuse.

Traditionally, schizophrenia has been subclassified into several categories, including paranoid, catatonic, hebephrenic, and undifferentiated. Paranoid schizophrenia is characterized by predominately delusions and hallucinations, with relatively preserved interpersonal abilities. Catatonic schizophrenia is characterized by predominant motor features, while hebephrenic schizophrenia is characterized by a shallow and silly display of emotions. Undifferentiated schizophrenia has predominately negative symptoms. For reasons that are not clear, the prevalence of catatonic and hebephrenic schizophrenia has decreased in the last few decades.

35.4.3. Epidemiology

The lifetime population prevalence of schizophrenia is about 1% (Gottesman, 1989). In a landmark transnational study, similar prevalence was found for schizophrenia in Africa, Asia, Europe, and the Americas (Jablensky and Sartorius, 1988). There is no influence of gender in schizophrenia, with women as likely to develop this condition as men. Males may have an earlier onset of illness, and a more severe course of illness. Some evidence suggests that the prevalence of schizophrenia may be decreasing over time, with fewer new cases of the illness reported. The age at onset of schizophrenia is late teens to early twenties. As in bipolar disorder, the onset of first symptoms after age 40 is rare.

35.4.4. Course of Illness

Schizophrenia is a chronic illness. Though clinical improvement in symptoms may occur, particularly with treatment,

remission of the illness is rare. Prior to developing overt symptoms of the illness, such as hallucinations and delusions, many persons with schizophrenia have prodromal symptoms. These include social isolation, idiosyncratic thinking, and feeling suspicious. Once established, schizophrenia is characterized by marked incapacity. Many persons with this condition are unemployable, homeless, and otherwise live on the fringes of society. Not uncommonly, the positive symptoms may ameliorate over the course of time, leaving negative residual symptoms, such as amotivation, to predominate.

Persons who suffer schizophrenia have intellectual impairment, having, on the average, an IQ that is one standard deviation below normal. Complications of schizophrenia include drug and alcohol abuse, depression, and suicide.

35.4.5. Etiology

Schizophrenia is in part a genetic illness. Several studies have consistently shown that monozygotic twins are three to six times more likely to be concordant for the illness than dizygotic twins. Further, there is a 5–10% prevalence of schizophrenia in first degree relatives of schizophrenics. Genetic studies have suggested linkage to chromosomes 22, 6, and 8 (McGuffin et al., 1995; Kendler and Diehl, 1993).

Other causes have also been suggested. There is an increase of schizophrenia in persons born during the winter months (Norquist and Narrow, 2000). Also, increased incidence of schizophrenia is noted in offspring of mothers who suffered influenza during the second trimester of pregnancy (Mednick et al., 1988). A viral hypothesis has been proposed, with some indirect evidence (Torey and Peterson, 1976; Crow, 1984). Finally, schizophrenia is associated with birth complications, such as transient perinatal hypoxia (Davies et al., 1998).

35.4.6. Neurobiology

The most widely replicated finding in schizophrenia is enlarged ventricles, and reduced brain volume (Weinberger et al., 1979; Pakkenberg, 1987). Functional neuroimaging studies have reported reduced blood perfusion of the frontal lobes during activation with tasks that involve executive function. Some postmortem studies report histological abnormalities, such as disorientation of pyramidal cells in the hippocampus (Falkai and Bogerts, 1986), though these findings have been difficult to replicate.

The predominant neurochemical hypothesis involves the neurotransmitter dopamine. This hypothesis was based on the observation that all drugs that are effective in ameliorating psychotic symptoms have a common mechanism of action in blocking the dopamine D2 receptor. Furthermore, the clinical antipsychotic potencies of these drugs are directly related to their affinities for the dopamine D2 receptor. Thus, a relative excess in dopamine is postulated to account for psychotic symptoms in schizophrenia. Demonstrating excess dopamine in schizophrenia has

proved difficult (Owen et al., 1984; Cookson et al., 1989). It is uncertain whether the total density of D2 receptors in schizophrenia is increased. However, recent evidence suggests that the functional state of D2 receptor (i.e., the state of the receptor having high-affinity for dopamine) may be elevated and this could help explain why many (if not most) individuals with schizophrenia are supersensitive to dopamine (Seeman et al., 2005).

A more recent neurochemical hypothesis involves glutamate. This was based on the finding that drugs which block the NMDA glutamate receptor, such as PCP, produce hallucinations, thought disorder, and cognitive deficits, as well as negative symptoms with great similarity to symptoms of schizophrenia (Wilkins, 1989; Meltzer, 1991). Again, demonstrating abnormal glutamate functioning in patients with schizophrenia has proved challenging. Serotonin (5-HT) is also implicated in schizophrenia, due to the mediation of the hallucinogenic effects of drugs such as LSD via 5-HT_{2A} receptors.

As well as hallucinations and delusions, schizophrenia is characterized by deficits in information processing. Schizophrenics have difficulty suppressing irrelevant environmental stimuli. This is referred to as sensory gating or prepulse inhibition, and commonly measured with auditory evoked potentials. When two stimuli, such as sounds, are presented within 30–500 msec, the response to the second stimulus rapidly decreases upon repeated presentations in healthy people, but not in persons with schizophrenia (Braff et al., 2001). This deficit is found in family members of patients with schizophrenia, and has been linked to the alpha-7 nicotinic receptor gene. The deficit is reversed by nicotine on an acute basis, and by some antipsychotic drugs. Alpha-7 nicotinic agonists are under development as treatment for schizophrenia (Martin et al., 2004).

35.4.7. Animal Models

Animal models of schizophrenia are intended to examine specific neurochemical or anatomical theories of the illness, and not to model the cluster of symptoms that characterizes the illness, since these are largely subjective. Models are divided into two types, pharmacological models and lesions models (Marcotte et al., 2001).

The pharmacological models are based on increasing activity of neurotransmitters considered to be involved in schizophrenia, such as dopamine, glutamate, and serotonin. Administration of dopamine agonists, 5-HT_{2A} agonists, and NMDA antagonists disrupts prepulse inhibition in a manner similar to that seen in schizophrenics. This effect is sensitive to some antipsychotic drugs (Geyer et al., 2001).

Lesion models are based on the idea that schizophrenia is, in part, a neurodegenerative or neurodevelopmental disorder. These lesions are generally neurotoxic, and have variable response to antipsychotic drugs (Marcotte et al., 2001). Recently, a novel model was studied in which pregnant mouse

dams received a single exposure to a cytokine releasing agent. The offspring demonstrated schizophrenic like behaviors, as well as deficits in prepulse inhibition and enhanced sensitivity to amphetamine (Meyer et al., 2005).

Improved animal models are needed, particularly for the “negative symptoms” of schizophrenia, such as amotivation, and the cognitive symptoms (Geyer and Ellenbroek, 2003).

35.4.8. Treatment

The primary treatment for schizophrenia involves use of antipsychotic medications. These are classified as “typical” or first generation, and “atypical.” The atypical antipsychotics differ from the typical in having relatively less extrapyramidal side effects, such as rigidity, dystonia (muscle spasm), akathisia (motor restlessness), and pseudo-Parkinsonian symptoms.

As discussed earlier, these agents are thought to produce their antipsychotic effect by blocking the dopamine D2 receptor in the CNS. These agents are not specific for the dopamine receptors and have various affinities, for example, for the muscarinic acetylcholine receptor, the α -1 adrenergic receptor and the H_1 histamine receptor. As a consequence they produce anticholinergic side effects of drug mouth, constipation and cycloplegia, and the adrenergic side effects of postural hypotension, and sedation; and the histaminergic effects of weight gain. The atypical antipsychotics have relatively greater affinity for serotonin receptors, and have demonstrated antidepressant effects in some cases.

These medications can exert a calming and tranquilizing effect with acute administration, and are used for these purposes in treating severely agitated patients. Their antipsychotic effects usually require treatment over the course of a few days or weeks. An exciting aspect of the atypical antipsychotics is their potential therapeutic efficacy for improving negative and cognitive symptoms of schizophrenia.

35.4.9. Immunological Correlates

Phospholipid abnormalities have been reported in schizophrenia, which may be due to altered immune function (du Bois et al., 2005). An intriguing concept is that in some cases schizophrenia may represent an autoimmune illness (Jones et al., 2005). Though the findings are not always consistent, dysregulation of immune system activity is noted in many studies in schizophrenia (Muller et al., 2000; Gaughran, 2002; Leweke et al., 2004).

Summary

Major depression, bipolar syndromes and schizophrenia are common and often severe mental illnesses. All three of these tend to have an onset in late adolescence or young adulthood. Major depression is characterized by persistent low mood and decreased interest and pleasure, as well as physical and psychological symptoms, including sleep disturbance,

low energy, and memory problems. Lifetime prevalence for major depressive disorder is about 8% for men and 16% for women. The etiology of major depressive disorder is in part genetic, and in part related to adverse stressful life events. The neurobiology of depressive disorders is linked to alterations in biogenic amine in brain, particularly norepinephrine and serotonin. Additionally, neuroendocrine abnormalities, particularly elevated cortisol, are well documented. Several animal models are well described for depressive disorders, most involving stress. Treatment of major depression can involve psychological intervention, particularly cognitive behavioral therapy, as well as use of antidepressant drugs. Most antidepressant drugs have effects to increase the levels of biogenic amines, but need to be administered on a repeated basis for several weeks for full therapeutic benefit.

Bipolar disorder is characterized by episodes of mania or hypomania, which include hyperactivity, decreased need for sleep, and a euphoric or irritable mood. Additionally, persons with bipolar disorder may have episodes of depression similar to those seen in major depressive disorder. The lifetime prevalence of severe bipolar disorder is about 1% and 3–5% if milder cases are included, afflicting men and women equally. Both bipolar disorder and major depressive disorder tend to be episodic, and in the periods of time between episodes, persons may experience few or no symptoms. The etiology of bipolar disorder is predominately genetic, with a 70% concordance in monozygotic twins. The neurobiology of bipolar disorder is less well understood, and few animal models have been developed. Treatment of bipolar disorder usually involves “mood stabilizer” medications, including lithium, and the anticonvulsants valproate and carbamazepine. At times, antidepressant and antipsychotic medications are also used.

Schizophrenia is a chronic and disabling illness, characterized by psychotic or “positive” symptoms, including hallucinations and delusions. Also, persons with schizophrenia usually have “negative” symptoms, including amotivation, less speech, and poor emotional response to stimuli. Schizophrenia affects about 1% of the population, with an etiology that is, in part, genetic, and possibly related to intrauterine problems. Neurobiological correlates of schizophrenia include enlarged ventricles, and the predominant neurochemical theories involve dopamine and glutamate. As in bipolar disorder, animal models are not well developed. The primary treatment of schizophrenia is with antipsychotic medications, usually the “atypical agents,” including clozapine, risperidone, and olanzapine.

Review Questions/Problems

1. The predominate feature of mood disorders is

- inappropriate or abnormal emotional state
- disturbance in thinking
- disturbances in perception
- hallucinations
- delusions

2. For a diagnosis of a major depressive disorder the patient must have experienced for at least two weeks of either a sustained low or depressed mood and/or
 - a. sleep disturbance
 - b. an appetite disturbance
 - c. a feeling of worthlessness or guilt
 - d. loss of energy, fatigue
 - e. suicidal ideation
 - f. decreased interest or pleasure
3. The prevalence for major depressive disorder is
 - a. greater for women than men
 - b. similar for women and men
 - c. is greater for Hispanics than Caucasians
 - d. is higher for Europeans than Asians
 - e. higher in married than divorced persons
4. Neurobiological studies suggest that primary neurotransmitter(s) involved in major depressive disorders is (are)
 - a. dopamine
 - b. serotonin
 - c. glutamate
 - d. norepinephrine
 - e. dopamine and serotonin
 - f. serotonin and norepinephrine
5. For a diagnosis of mania a person must demonstrate
 - a. decreased need for sleep
 - b. racing thoughts
 - c. hallucinations
 - d. increased goal directed activity
 - e. a distinct period of elevated, expansive, or irritable mood, as well as other symptoms
 - f. grandiosity or increased self-esteem
6. Which one of the following classes of drugs is first line of treatment for bipolar disorders?
 - a. monoamine oxidase inhibitors
 - b. selective serotonin reuptake inhibitors
 - c. cortisol
 - d. mood stabilizers
 - e. antibiotics
7. Drugs or drugs of abuse that can produce a manic like state include
 - a. antiepileptic drugs
 - b. lithium
 - c. amphetamine
 - d. antipsychotics
 - e. anticholinergic drugs
 - f. antibiotics
8. Common side-effects of the typical antipsychotics are
 - a. antidepressant effects
 - b. insomnia
 - c. spasticity
 - d. muscle weakness
 - e. parkinsonian-like symptoms
9. The lifetime population prevalence for major depressive disorder is
 - a. 50%
 - b. 5–25%
 - c. 2–3%
 - d. 3–4%
 - e. unable to determine due to complexity of symptoms
10. The etiology of mood disorders is best conceptualized as involving
 - a. poor parenting
 - b. excessive life stress
 - c. genetic predisposition plus environmental factors
 - d. maladaptive stress response
 - e. excessive norepinephrine
11. A commonly replicated finding in major depressive disorder is
 - a. high cortisol
 - b. high norepinephrine
 - c. high dopamine
 - d. low sodium
 - e. low cortisol
12. Major depressive disorder is
 - a. familial and probably genetic
 - b. due entirely to stress
 - c. not responsive to treatment
 - d. related to low cortisol levels
 - e. shown to be due to excessive biogenic amines
13. A well-established biological correlate for major depressive disorder involves
 - a. decreased testosterone
 - b. decreased protein kinase
 - c. increased testosterone
 - d. increased sodium
 - e. none of the above
14. Animal models of depressive disorders include
 - a. learned helplessness
 - b. forced swim test
 - c. chronic mild stress
 - d. tail suspension test
 - e. all of the above
15. Drugs used as first line treatment for major depressive disorder include
 - a. lithium
 - b. neosporin
 - c. olanzapine
 - d. fluoxetine
 - e. chlordiazepoxide

16. Drugs used to treat bipolar disorder include

- a. lithium
- b. valproate
- c. carbamazepine
- d. antidepressants
- e. all of the above

17. Persons with bipolar disorder frequently experience

- a. decreased need for sleep
- b. pressured speech
- c. elevated, expansive, or irritable mood
- d. increased goal directed activity
- e. all of the above

18. The prevalence of bipolar disorder is

- a. greater among ethnic minorities
- b. greater in European countries
- c. less in African-American communities
- d. greater in women
- e. about 1% in all cultures studied

19. The etiology of bipolar disorder is

- a. dependent upon race and social status
- b. clearly genetic
- c. dependent upon time of birth
- d. dependent upon country of origin
- e. not due to any genetic factors

20. The diagnosis of schizophrenia requires

- a. hallucinations
- b. delusions
- c. disturbed thought
- d. decrease social and vocational abilities
- e. all of the above

Molecular Pathogenesis for Schizophrenia and Major Depression

Norbert Müller and Markus J. Schwarz

Keywords Schizophrenia; Major depression; Th1/Th2 balance; Pro-inflammatory cytokines; NMDA hypothesis; Glutamate; Serotonin; Tryptophan; Kynurenine; Kynurenic acid; HPA axis

36.1. Introduction

In schizophrenia, dopaminergic hyperfunction in the limbic system and dopaminergic hypofunction in the frontal cortex are discussed to be the main neurotransmitter disturbances. Recent research provides further insight that glutamatergic hypofunction might be the cause for this dopaminergic dysfunction. In major depression, in contrast, glutamatergic hyperfunction seems to be closely related to the lack of serotonergic and noradrenergic neurotransmission and to the core symptoms of major depression. Therefore, glutamatergic dysfunction seems to be a common pathway in the neurobiology of schizophrenia and depression. The function of the glutamatergic system is closely related to the immune system and to the tryptophan-kynurenine metabolism, which both seem to play a key role in the pathophysiology of schizophrenia and major depression (Müller and Schwarz, 2006, 2007).

36.2. Glutamatergic Neurotransmission and NMDA-Receptor Function in Schizophrenia and Major Depression

36.2.1. Schizophrenia

A disturbance in the dopaminergic neurotransmission plays a key-role in the pathogenesis of schizophrenia (Carlsson, 1988). Most drugs ameliorating psychotic symptoms act as dopamine receptor blockers, in particular D2 receptor blockers. In light

of only a portion of patients responding to antipsychotic drugs and unsatisfactory long term outcomes, attempts to explain the disease solely in terms of dopaminergic dysfunction leave many aspects of schizophrenia unsolved.

The glutamate hypothesis of schizophrenia postulates an equilibrium between inhibiting dopaminergic and inhibiting glutamatergic neurons; the model of a cortico-striato-thalamo-cortical control loop integrates the glutamate hypothesis with neuroanatomical aspects on the pathophysiology of schizophrenia (Carlsson et al., 2001). Hypofunction of the glutamatergic cortico-striatal pathway is associated with opening of the thalamic filter, which leads to an uncontrolled flow of sensory information to the cortex and to psychotic symptoms. Hypofunction of the glutamatergic neurotransmitter system as a causal mechanism in schizophrenia was first proposed due to the observation of low concentrations of glutamate in the CSF of schizophrenic patients (Kim et al., 1980).

Treatment with NMDA receptor antagonists leads to a marked, dose-dependent increase of amphetamine-induced dopamine release (Miller and Abercrombie, 1996). In schizophrenics, this amphetamine-induced dopamine release is much higher compared to healthy controls (Laruelle et al., 1996). This observation is in accordance with the view that activation of the nigrostriatal dopamine system can take place by opposing activation of inhibitory striatonigral GABAergic projection neurons (Carlsson et al., 2001).

Phencyclidine (PCP), Ketamin, and MK-801 all block the N-methyl-D-aspartate (NMDA) receptor complex and are associated with schizophrenia-like symptoms through hypofunction of the glutamatergic neurotransmission (Krystal et al., 1994; Olney and Farber, 1995). Other NMDA antagonists have psychotogenic properties, too (CPP, CPP-ene, CGS 19755). NMDA receptor hypofunction can explain schizophrenic positive and negative symptoms, cognitive deterioration and structural brain changes (Olney and Farber, 1995).

Findings of decreased plasma levels of the NMDA co-agonist glycine in schizophrenics and a correlation of glycine levels with schizophrenic negative symptoms are in line with decreased NMDA-receptor function (Sumiyoshi et al., 2004). Baseline glycine levels predicted the treatment outcome of clozapine on negative symptoms (Sumiyoshi et al., 2005). Clinical investigations targeted the glycine co-agonistic site of the NMDA receptor by administering the amino acids glycine or D-serine, or a glycine pro-drug such as milacemide (Tamminga et al., 1992). Some of these studies have yielded positive results, particularly against the schizophrenic deficit syndrome (Heresco-Levy et al., 1999).

36.2.2. Major Depression

Overwhelming evidence collected over the last 40 years suggests that disturbances in the serotonergic and noradrenergic neurotransmission are the crucial factor in the pathogenesis of major depression (Matussek, 1966; Coppen and Swade, 1988). The common therapeutic mechanism of antidepressant drugs is the increase of serotonergic and/or noradrenergic neurotransmission. Intense research, however, has not yet been able to discover the mechanisms leading to disturbances of the serotonergic/noradrenergic neurotransmission.

Although the glutamatergic system may influence directly or indirectly the serotonergic and noradrenergic neurotransmission, only few data have been published with regard to this interaction. NMDA receptor antagonists increase the serotonin levels in the brain (Yan et al., 1997; Martin et al., 1998). Several studies showed an increased activity of the glutamatergic system in the peripheral blood of depressive patients (Kim et al., 1982; Altamura et al., 1993; Mauri et al., 1998). This result could not be replicated by all authors (Maes et al., 1998). The inconsistency of the findings, however, might be due to methodological problems (Kugaya and Sanacora, 2005).

Support for increased glutamatergic activity in depression comes from magnetic resonance spectroscopy: Elevated glutamate levels were found in the occipital cortex of unmedicated subjects with major depression (Sanacora et al., 2004a). An increased level of a certain neurotransmitter is often associated with a down-regulation of the respective receptor. Accordingly, a reduced glycine binding site of the NMDA receptor was found in the brains of suicide victims and patients with depression (Nowak et al., 1995; Nudmamud-Thanoi and Reynolds, 2004). Moreover, a decrease in the NMDA agonistic MK-801 binding in bipolar patients was observed (Scarr et al., 2003).

Consistent with the view that an increased activity of the glutamatergic system and NMDA receptor agonism is associated with depressed mood, a reduction of the glutamatergic activity through NMDA receptor antagonism might exert antidepressant effects. NMDA antagonists such as MK-801 (Maj et al., 1992; Trullas and Skolnick, 1990), ketamine (Yilmaz et al., 2002), memantine (Ossowska et al., 1997), and others (Kugaya and Sanacora, 2005) exhibited antidepressant effects

in different animal models. In humans, D-cycloserine, a partial NMDA receptor agonist, which acts as a NMDA receptor antagonist in high doses, demonstrated antidepressant effects in high doses (Crane, 1959). Slight antidepressive effects have also been observed with amantadine (Huber et al., 1999; Stryker et al., 2003). Moreover, preliminary data show antidepressant effects of the NMDA receptor antagonist ketamine (Kudoh et al., 2002; Ostroff et al., 2005) and riluzole, an antiglutamatergic agent believed to increase the glutamatergic uptake into the astrocytes, is under intensive investigation for its antidepressant efficacy (Frizzo et al., 2004). A recent series of open-labelled studies and case reports demonstrated the efficacy of riluzole (Coric et al., 2003; Sanacora et al., 2004b; Zarate et al., 2004, 2005).

36.3. Inflammation in Schizophrenia and Depression

36.3.1. Schizophrenia

Infection during pregnancy, in particular in the second trimester, in mothers of off-springs later developing schizophrenia has been repeatedly described (Brown et al., 2004; Buka et al., 2001; Westergaard et al., 1999). As opposed to any single pathogen, the immune response, itself, of the mother may be related to the increased risk for schizophrenia in the offspring (Zuckerman and Weiner, 2005). Indeed, increased IL-8 levels of mothers during the second trimester were associated with an increased risk for schizophrenia in the offspring (Brown et al., 2004). A fivefold increased risk for developing psychoses later on, however, was also observed after infection of the CNS in early childhood (Gattaz et al., 2004; Koponen et al., 2004).

Signs of inflammation were found in schizophrenic brains (Körschenhausen et al., 1996), and the term 'mild localized chronic encephalitis' to describe a slight but chronic inflammatory process in schizophrenia was proposed (Bechter et al., 2003).

36.3.2. Major Depression

An inflammatory model of major depression (MD) is 'sickness behaviour', the reaction of the organism to infection and inflammation. Sickness behaviour is characterised by weakness, malaise, listlessness, inability to concentrate, lethargy, decreased interest in the surroundings, and reduced food intake—all of which are depression-like symptoms. The sickness-related psychopathological symptomatology during infection and inflammation is mediated by proinflammatory cytokines such as IL-1, IL-6, tumor-necrosis-factor- α (TNF- α), and IFN- γ . The active pathway of these cytokines from the peripheral immune system to the brain is via afferent neurons and through direct targeting of the amygdala and other brain regions after diffusion at the circumventricular organs and choroid plexus (Dantzer, 2001).

Undoubtedly, there is a strong relationship between the cytokine system and the neurotransmitter system, but a more differentiated analysis may be required to understand the specific mechanisms underlying the heterogeneous disease entity of MD.

In humans, the involvement of cytokines in the regulation of the behavioural symptoms of sickness behaviour has been studied by application of the bacterial endotoxin LPS to human volunteers (Reichenberg et al., 2001). LPS, a potent activator of proinflammatory cytokines, was found to induce mild fever, anorexia, anxiety, depressed mood, and cognitive impairment. The levels of anxiety, depression and cognitive impairment were found to be related to the levels of circulating cytokines (Reichenberg et al., 2001; Reichenberg et al., 2002).

Mechanisms that contribute to inflammation and can cause depressive states are:

A direct influence of proinflammatory cytokines on the serotonin and noradrenalin metabolism

1. An imbalance of the type-1 – type-2 immune response leading to an increased tryptophan and serotonin metabolism by activation of IDO in the CNS, which is associated with
2. A decreased availability of tryptophan and serotonin,
3. A disturbance of the kynurenine metabolism with an imbalance in favour of the production of the NMDA-receptor agonist quinolinic acid, and
4. An imbalance in astrocyte- and microglial activation associated with increased production of quinolinic acid.

Effects of antidepressants on the immune function support this view. The mechanisms and the therapeutic implications will be discussed in the following paragraphs.

36.4. Polarized Type-1 and Type-2 Immune Responses

36.4.1. Reduced Type-1 Immune Response in Schizophrenia

A well established finding in schizophrenia is the decreased *in vitro* production of IL-2 and IFN- γ (Wilke et al., 1996; Müller et al., 2000), reflecting a blunted production of type-1 cytokines. Decreased levels of neopterin, a product of activated monocytes/macrophages, also point to a blunted activation of the type-1 response (Sperner-Unterwieser et al., 1999). The decreased response of lymphocytes after stimulation with specific antigens reflects a reduced capacity for a type-1 immune response in schizophrenia, as well (Müller et al., 1991). Decreased levels of soluble (s)ICAM-1, as found in schizophrenia, also represent an under-activation of the type-1 immune system (Schwarz et al., 2000). Decreased levels of the soluble TNF-receptor p55—mostly decreased when TNF- α is decreased—were observed, too (Haack et al., 1999).

A blunted response of the skin to different antigens in schizophrenia was observed before the era of antipsychotics

(Molholm, 1942). This finding could be replicated in unmedicated schizophrenic patients using a skin test of the cellular immune response (Riedel et al., 2007).

36.4.2. Increased Type-2 Immune Response in Schizophrenia

Several reports described increased serum IL-6 levels in schizophrenia. IL-6 serum levels might be especially high in patients with an unfavourable course of the disease (Müller et al., 2000). IL-6 is a product of activated monocytes and of the activation of the type-2 immune response. Moreover, several other signs of activation of the type-2 immune response are described in schizophrenia, including the increased production of IgE and an increase of IL-10 serum levels (Cazzullo et al., 1998; Schwarz et al., 2001). In the cerebrospinal fluid (CSF), IL-10 levels were found to be related to the severity of the psychosis (van Kammen et al., 1997).

The key cytokine of the type-2 immune response is IL-4. Increased levels of IL-4 in the CSF of juvenile schizophrenic patients have been reported (Mittleman et al., 1997), which supports that the increased type-2 response in schizophrenia is not only a phenomenon of the peripheral immune response.

36.4.3. Increased Proinflammatory Type-1 Cytokines in Major Depression

Characteristics of the immune activation in MD include increased numbers of circulating lymphocytes and phagocytic cells, upregulated serum levels of indicators of activated immune cells (neopterin, soluble IL-2 receptors), higher serum concentrations of positive acute phase proteins (APP's), coupled with reduced levels of negative APP's, as well as increased release of proinflammatory cytokines, such as IL-1, IL-2, TNF- α , and IL-6 through activated macrophages and IFN- γ through activated T-cells (Müller et al., 1993; Maes et al., 1995a, b; Irwin 1999; Nunes et al., 2002; Müller and Schwarz, 2002; Mikova et al., 2001). Increased numbers of peripheral mononuclear cells in MD have been described by different groups of researchers (Herbert and Cohen, 1993; Seidel et al., 1996b; Rothermundt et al., 2001).

Neopterin is a sensitive marker of the cell-mediated type-1 immunity. The main source of neopterin is monocytes/macrophages. In accordance with the findings of increased monocytes/macrophages, an increased secretion of neopterin has been described by several groups of researchers (Duch et al., 1984; Dunbar et al., 1992; Maes et al., 1994; Bonaccorso et al., 1998).

The increased plasma concentrations of the proinflammatory cytokines IL-1 and IL-6 observed in depressed patients was found to correlate with the severity of depression and with measures of HPA axis hyperactivity (Maes et al., 1993; Schiepers et al., 2005). As genetics plays a role in MD, the genetics of the immune system in relation to MD has also been investigated. Certain cytokine gene polymorphisms, e.g.

in genes coding for IL-1 and TNF- α may confer a greater susceptibility to develop MD (Jun et al., 2003; Fertuzinhos et al., 2004; Rosa et al., 2004).

The production of IL-2 and IFN- γ is the typical marker of a type-1 immune response. In contrary to schizophrenia, IFN- γ is produced in greater amounts by lymphocytes of patients with MD than of healthy controls (Seidel et al., 1996a). Higher plasma levels of IFN- γ in depressed patients, accompanied by lower plasma tryptophan availability were described (Maes et al., 1994). Data on IL-2 in major depression are mainly restricted to the estimation of its soluble receptor sIL-2R in the peripheral blood. Increased sIL-2R levels reflect an increased production of IL-2. The blood levels of sIL-2R were repeatedly found to be increased in MD patients (Sluzewska et al., 1996; Maes et al., 1995a, b).

Since different pathologies may underlie the syndrome of depression, different immunological states might be involved. Indeed, different types of MD were observed to exhibit different immune profiles: The subgroup of melancholic depressed patients showed a decreased type-1 activation—as it was observed in schizophrenic patients (Müller and Schwarz, 2007)—while the non-melancholic depressed patients showed signs of inflammation such as increased monocyte count and increased levels of α_2 -macroglobulin (Rothermundt et al., 2001).

Suicidality, observed in a very high amount of depressed patients, seems to be associated with an 'idealtypic' immune activation pattern for depression, since clinical studies have observed higher levels of type-1 cytokines in suicidal patients. In a small study, distinct associations between suicidality and type-1 immune response and a predominance of type-2 immune parameters in non-suicidal patients were observed (Mendlovic et al., 1999). An epidemiological study hypothesized that high IL-2 levels are associated with suicidality (Penttinen, 1995). There have been descriptions of increased levels of serum sIL-2R in medication-free suicide attempters irrespective of the psychiatric diagnosis (Nassberger and Traskman-Bendz, 1993), and treatment with high-dose interleukin-2 has been associated with suicide in a case report (Baron et al., 1993).

These data show that possible different immune states within the 'syndrome' MD have to be more differentiated. The predominant pro-inflammatory, type-1 dominated immune state described in MD maybe an 'idealtypic' state restricted to a majority of patients suffering from MD. Therefore, those and other methodological concerns have to be regarded carefully in future studies.

36.5. Somatic States Associated with Depression and a Proinflammatory Immune Response as Psychoneuroimmunological Model Diseases

36.5.1. Medical Illness Condition

Illness-associated depressive symptoms may not merely be a psychological reaction to the pain, distress and incapacitation that are associated with the physical disease, but may

be directly caused by immune activation and the secretion of cytokines. These include acute and chronic infectious conditions (Meijer et al., 1988; Müller et al., 1992; Hall and Smith, 1996) as well as non-infectious conditions associated with chronic inflammation, such as rheumatoid arthritis, cancer and MS (Yirmiya et al., 1999; Pollak et al., 2000). Indeed, several studies have shown that immune dysregulation preceeds the development of depression (Sakic et al., 1996; Yirmiya et al., 1999; Yirmiya, 2000; Pollak et al., 2000).

36.5.2. Therapies Using Type-1 Cytokines

The same mechanism seems to be responsible for depressive states associated with cytokine therapy. Depression is a common side-effect of therapy with IFN- α and IL-2 (Bonaccorso et al., 2002; Schäfer et al., 2004). During these therapies, the enzyme indoleamine 2,3-dioxygenase (IDO) is activated and the tryptophan degradation increases. The psychopathological changes are related to the enhanced tryptophan metabolism and IDO activity: patients developing more severe depressive symptoms during INF- α showed a more pronounced increase in tryptophan metabolism (Bonaccorso et al., 2002; Capuron et al., 2002, 2003). Depression, also a common side-effect during therapy with IFN- β , often limits the use of IFN- β in the therapy of multiple sclerosis (Patten et al., 2005); although not a classical type-1 cytokine, IFN- β , too, leads to an activation of IDO, thereby provoking depressive symptoms (Amirkhani et al., 2005).

36.5.3. Pregnancy and Delivery

Pregnancy is immunologically characterized by a dominance of the type-2 immune response of the mother. In order to protect the fetus from abortion, the maternal organism develops immune tolerance against the non-self organism of the baby (Marzi et al., 1996; Saito et al., 1999). After delivery an activation of the type-1 response of the maternal immune system occurs (Maes et al., 2002; Ostensen et al., 2005). This type-1 dominated maternal immune rebalancing is associated with the postpartum blues (Maes et al., 2002), a state found in 20–75% of mothers (Stein, 1980; Josefsson et al., 2001), or the postpartum depression, a state found in 10–15% of mothers (O'Hara and Swain, 1996). After delivery, an increase of the proinflammatory immune response was described (Maes et al., 2002; Ostensen et al., 2005). Accordingly, postpartum blues is associated with increased activation of the proinflammatory immune response, increased activity of the IDO and a delay in the increase of postpartum tryptophan-levels compared to mothers without 'the blues' (Maes et al., 2002; Kohl et al., 2005). Symptoms of depression and anxiety in the early puerperum are significantly related to the increase of the proinflammatory cytokine IL-8 (Maes et al., 2002). Postpartum depression is associated with the activation of the proinflammatory type-1 immune response and a lack of tryptophan (Gard et al., 1986; Abou-Saleh et al., 1999).

36.6. Therapeutic Mechanisms and the Type-1/Type-2 Imbalance in Schizophrenia and Depression

36.6.1. Schizophrenia: Anti-Psychotic Drugs Rebalance the Type-1/Type-2 Imbalance

In-vitro studies show that the blunted IFN- γ production becomes normalized after therapy with neuroleptics (Wilke et al., 1996). An increase of 'memory cells' (CD4⁺ CD45RO⁺ cells)—one of the main sources of IFN- γ production—during anti-psychotic therapy with neuroleptics was observed by different groups (Müller et al., 1997b). Additionally, an increase of soluble IL-2 receptors (sIL-2R)—the increase reflects an increase of activated, IL-2 bearing T-cells—during anti-psychotic treatment was described (Müller et al., 1997a). The reduced sICAM-1 levels show a significant increase during short term anti-psychotic therapy (Schwarz et al., 2000) and the ICAM-1 ligand leucocyte function antigen-1 (LFA-1) shows a significantly increased expression during anti-psychotic therapy (Müller et al., 1999). The increase of TNF- α and TNF- α receptors during therapy with clozapin was observed repeatedly (Pollmächer et al., 2001). Moreover, the blunted reaction to vaccination with salmonella typhii was not observed in patients medicated with anti-psychotics (Ozek et al., 1971). Recently, an elevation of IL-18 serum levels was described in medicated schizophrenics (Tanaka et al., 2000). Since IL-18 plays a pivotal role in the type-1 immune response, this finding is consistent with other descriptions of type-1 activation during antipsychotic treatment.

Regarding the type-2 response, several studies point out that anti-psychotic therapy is accompanied by a functional decrease of the IL-6 system (Maes et al., 1997; Müller et al., 2000).

36.6.2. Therapeutic Techniques in Depression are associated with Downregulation of the Proinflammatory Immune Response

36.6.2.1. Antidepressant Pharmacotherapy

A modulatory, predominantly inhibitory effect of serotonin reuptake inhibiting drugs on activation of proinflammatory immune parameters was demonstrated in animal experiments (Bengtsson et al., 1992; Song and Leonard, 1994; Zhu et al., 1994).

Several antidepressants seem to be able to induce a shift from a type-1 to a type-2, from a proinflammatory to an anti-inflammatory immune response, since the ability of different antidepressants (sertraline, clomipramine, trazodone) to reduce the IFN- γ /IL-10 ratio significantly was shown in vitro. These drugs reduced the IFN- γ production significantly, while sertraline and clomipramine additionally raised the IL-10 production (Maes et al., 1999). Regarding other in-vitro studies, a significantly reduced production of IFN- γ , IL-2, and sIL-2R was found after antidepressant treatment compared to pre-treatment values (Seidel et al., 1995, b). A down-regulation

of the IL-6 production was observed during amitriptyline treatment; in treatment-responders, the TNF- α production decreased to normal (Lanquillon et al., 2000). There are also studies, however, showing no effect of antidepressants to the in-vitro stimulation of cytokines (overview: (Kenis and Maes, 2002), but methodological issues have to be taken into account. There is significant evidence suggesting that antidepressants of different classes show a down-regulation of the type-1 cytokine production in-vitro (Kenis and Maes, 2002).

Regarding serum levels, several researchers observed a reduction of IL-6 during treatment with the serotonin reuptake inhibitor fluoxetine (Sluzewska et al., 1995). A decrease of IL-6 serum levels during therapy with different antidepressants has been observed by other researchers (Frommberger et al., 1997). On the other hand, other groups did not find any effect of certain antidepressants on serum levels of different cytokines (Maes et al., 1995a, 1997).

Since IL-6 stimulates Prostaglandin E₂ (PGE₂) and antidepressants inhibit the IL-6 production, an inhibiting action of antidepressants on PGE₂ would be expected, too (Pollak and Yirmiya, 2002). Over twenty years ago it was suggested that antidepressants inhibit PGE₂ (Mtabaji et al., 1977). A recent in-vitro study showed that both tricyclic antidepressants and selective serotonin inhibitors attenuated cytokine-induced PGE₂ and nitric oxide production by inflammatory cells (Yaron et al., 1999).

36.6.2.2. Non-Pharmacological Therapies: Electro-Convulsive Therapy and Sleep Deprivation

Electroconvulsive therapy (ECT) was found to downregulate increased levels of the proinflammatory cytokine TNF- α in patients with MD (Hestad et al., 2003).

An immune analysis during sleep showed an increase of the type-1 monocyte derived cytokines TNF- α and IL-12 and a decrease of the type-2 IL-10 producing monocytes (Dimitrov et al., 2004). In contrary, continuous wakefulness blocked the increase of type-1 and decrease of type-2 cytokines (T. Lange and S. Dimitrov, personal communication). Thus, sleep deprivation may exert therapeutic effects through a low suppression of type-1 cytokines.

36.7. Divergent Effects of the Role of Type-1/Type-2 Immune Activation are associated with Different Effects to the Kynurenine Metabolism in Schizophrenia and Depression

36.7.1. Schizophrenia

The only known naturally occurring NMDA receptor antagonist in the human CNS is kynurenic acid (KYNA; Stone, 1993). KYNA is one of the three neuroactive intermediate products of the kynurenine pathway. Kynurenine (KYN) is

the primary major degradation product of tryptophan (TRP). While the excitatory KYN metabolites 3-hydroxykynurenine (3HK) and quinolinic acid are synthesized from KYN en route to NAD, KYNA is formed in a dead end side arm of the pathway (Schwarcz and Pellicciari, 2002).

KYNA acts both, as a blocker of the glycine coagonistic site of the NMDA receptor (Kessler et al., 1989) and as a non-competitive inhibitor of the $\alpha 7$ nicotinic acetylcholine receptor (Hilmas et al., 2001).

The production of KYNA is regulated by IDO and tryptophan 2,3-dioxygenase (TDO). Both enzymes catalyze the first step in the pathway, the degradation from tryptophan to kynurenine. Type-1 cytokines, such as IFN- γ and IL-2 stimulate the activity of IDO (Grohmann et al., 2003). Figure 36.1 shows the relationship between cytokines, enzymes of the tryptophan metabolism, and formation of neuroactive intermediates.

There is a mutual inhibitory effect of TDO and IDO: a decrease in TDO activity occurs concomitantly with IDO induction, resulting in a coordinate shift in the site (and cell types) of tryptophan degradation (Takikawa et al., 1986). While it has been known for a long time that IDO is expressed in different types of CNS cells, TDO was thought for many years to be restricted to liver tissue. It is known today, however, that TDO is also expressed in CNS cells, probably restricted to astrocytes (Miller et al., 2004).

The type-2 or Th-2 shift in schizophrenia may result in two functional consequences: The expression of IDO, normally increased by type-2 cytokines, in particular INF- γ , is down-regulated, while TDO is up-regulated. The type-1/type-2 imbalance is associated with the IDO/TDO imbalance.

Additionally, the type-1/type-2 imbalance is associated with the activation of astrocytes and an imbalance in the activation of astrocytes/microglial cells (Aloisi et al., 2000). The functional overweight of astrocytes may lead to a further accumulation of KYNA.

Indeed, a study referring to the expression of IDO and TDO in schizophrenia showed exactly the expected results. An increased expression of TDO compared to IDO was observed in schizophrenic patients and the increased TDO expression was found, as expected, in astrocytes, not in microglial cells (Miller et al., 2004).

36.7.2. Major Depression

The enzyme indoleamine 2,3-dioxygenase (IDO) metabolizes tryptophan to kynurenine, kynurenine is then converted to quinolinic acid via the intermediate 3-HK by the enzyme kynurenine hydroxylase. Both IDO and kynurenine hydroxylase are induced by the type-1 cytokine IFN- γ . The activity of IDO is an important regulatory component in the control of lymphocyte proliferation, the activation of the type-1 immune response and the regulation of the tryptophan metabolism (Mellor and Munn, 1999). It induces a halt in the lymphocyte cell cycle due to the catabolism of tryptophan (Munn et al., 1999). In contrast to the type-1 cytokines, the type-2 cytokines IL-4 and IL-10 inhibit the IFN- γ -induced IDO-mediated tryptophan catabolism (Weiss et al., 1999). IDO is located in several cell types including monocytes and microglial cells (Alberati et al., 1996). An IFN- γ -induced, IDO-mediated decrease of CNS

FIGURE 36.1. Neuroimmune interactions of Kynurenine intermediates. Metabolism of tryptophan via the kynurenine pathway leads to several neuroactive intermediates: Kynurenic acid (synthesised by kynurenine aminotransferase, KAT) has neuroprotective properties through antagonism at the NMDA receptor. Quinolinic acid, in contrast, is a NMDA receptor agonist. Both, 3-hydroxykynurenine (3-OH-kynurenine) and quinolinic acid can induce neurodegeneration and apoptosis through induction of excitotoxicity and generation of neurotoxic radicals, respectively. Activity of the key enzyme of the kynurenine pathway, indoleamine 2,3-dioxygenase (IDO), and of the 3-OH-kynurenine forming enzyme kynurenine monooxygenase (KMO) is induced by proinflammatory cytokines like interferon- γ (IFN- γ) and inhibited by anti-inflammatory cytokines like interleukin-4 (IL-4). Serotonin is normally degraded to 5-hydroxyindoleacetic acid (5-HIAA), but the indole ring of serotonin can also be cleaved by IDO. (green arrows = activation; red arrows = inhibition.)

tryptophan availability may lead to a serotonergic deficiency in the CNS, since tryptophan availability is the limiting step in the serotonin synthesis. Other proinflammatory molecules such as PGE₂ or TNF- α , however, induce synergistically with IFN- γ the increase of IDO activity (Braun et al., 2005; Kwidzinski et al., 2005; Robinson et al., 2005). Therefore, not only IFN- γ and type-1 cytokines, but also other proinflammatory molecules induce IDO activity. Since increased levels of PGE₂ and TNF- α were described in MD, other proinflammatory molecules contribute to IDO activation and tryptophan consumption, too (e.g. Linnoila et al., 1983; Mikova et al., 2001).

One of the most consistent findings in biochemical research dealing with mental disorders is that some patients with low 5-hydroxyindoleacetic acid (5-HIAA)—the metabolite of serotonin—in CSF are prone to commit suicide (Lidberg et al., 2000; Mann and Malone, 1997; Nordstrom et al., 1994). This gives additional evidence for a possible link between the type-1 cytokine IFN- γ and the IDO-related reduction of serotonin availability in the CNS of suicidal patients.

A recent study showed that immunotherapy with IFN- α was followed by an increase of depressive symptoms and serum kynurenine concentrations on the one hand, and reduced concentrations of tryptophan and serotonin on the other hand (Bonaccorso et al., 2002). The kynurenine/tryptophan ratio, which reflects the activity of IDO, increased significantly. Changes in depressive symptoms were significantly positively correlated with kynurenine and negatively correlated with serotonin concentrations (Bonaccorso et al., 2002). This study and others (Capuron et al., 2003) clearly show that the IDO activity is increased by IFN, leading to an increased kynurenine production and a depletion of tryptophan and serotonin. The further metabolism of kynurenine, however, seems to play an additional crucial role for the psychopathological states.

In addition to the effects of the proinflammatory immune response on serotonin metabolism, other neurotransmitter systems, in particular the catecholaminergic system, are involved in depression, too. Although the relationship of immune activation and the lack of catecholaminergic neurotransmission has not been well studied, the increase of the monoamino-oxidase (MAO) activity, which leads to decreased noradrenergic neurotransmission, might be an indirect effect of the increased production of kynurenine and quinolinic acid (Schiepers et al., 2005).

36.8. Astrocytes, Microglia, and Type-1/Type-2 Response

The cellular sources for the polarized immune response in the CNS are astrocytes and microglia cells. Microglial cells, deriving from peripheral macrophages, secrete preferably type-1 cytokines such as IL-12, while astrocytes inhibit the production of IL-12 and ICAM-1 and secrete the type-2 cytokine IL-10 (Xiao and Link, 1999; Aloisi et al., 1997). Therefore, the type-1/type-2 imbalance in the CNS seems to be represented

by the imbalance in the activation of microglial cells and astrocytes. The view of an over-activation of astrocytes in schizophrenia is supported by the finding of increased levels of S100B—a marker of astrocyte activation—independent of the medication state of the schizophrenic patients (Lara et al., 2001; Schroeter et al., 2003; Schmitt et al., 2005; Rothermundt et al., 2004a, b). Microglia activation, however, was only found in a small percentage of schizophrenics and is speculated to be a medication effect (Bayer et al., 1999). A type-1 immune activation as an effect of neuroleptic treatment has repeatedly been observed.

Since the type-1 activation predominates the response of the peripheral immune system in depression, a dominance of microglial activation compared to astrocyte activation should be observed in depression. Glial reductions were consistently found in brain circuits known to be involved in mood disorders, such as in the limbic and prefrontal cortex (Cotter et al., 2002; Ongur et al., 1998; Rajkowska et al., 1999, 2001; Rajkowska, 2003). Although several authors did not differentiate between microglial and astrocytic loss, this difference is crucial due to the different effects of the type-1/type-2 immune response. Recent studies, however, show that astrocytes are diminished in patients suffering from depression (Johnston-Wilson et al., 2000; Miguel-Hidalgo et al., 2000; Si et al., 2004), although the data are not fully consistent (Davis et al., 2002). A loss of astrocytes was in particular observed in younger depressed patients: the lack of GFAP-immunoreactive astrocytes reflects a lowered activity of responsiveness in those cells (Miguel-Hidalgo et al., 2000). A loss of astrocytes was found in many cortical layers and in different sections of the dorsolateral prefrontal cortex in depression (Rajkowska, 2005).

Moreover, a loss of astrocytes is associated with an impaired reuptake of glutamate from the extracellular space into astrocytes by high affinity glutamate transporters, (Choudary et al., 2005; Gegelashvili et al., 2001). Impaired glutamate reuptake from the synaptic cleft by astroglia prolongs synaptic activation by glutamate (Auger and Attwell, 2000; Danbolt, 2001). Accordingly, increased glutamatergic activity was repeatedly observed in patients with depression (Sanacora et al., 2004a).

36.9. The Glutamate System in Schizophrenia and Depression

36.9.1. The Glutamate System in Schizophrenia: Kynurenic Acid as a Schizophrenogenic Substance

In contrast to microglial cells, which produce quinolinic acid, astrocytes play a key role in the production of kynurenic acid (KYNA) in the CNS. Astrocytes are the main source of KYNA (Heyes et al., 1997). The cellular localization of the kynurenine metabolism is primarily in macrophages and microglial cells, but also in astrocytes (Speciale and Schwarcz, 1993; Kiss et al., 2003). KYN-OHse, however, a critical enzyme in the

kynurenine metabolism, is absent in human astrocytes (Guillemin et al., 2001). Accordingly, it has been described that astrocytes cannot produce the product 3HK but they are able to produce large amounts of early kynurenine metabolites, such as KYN and KYNA (Guillemin et al., 2001). This supports the observation that inhibition of KYN-OHse leads to an increase of the KYNA production in the CNS (Chiarugi et al., 1996). The complete metabolism of kynurenine to quinolinic acid is observed only in microglial cells, not in astrocytes. Therefore, due to the lack of KYN-OHse, KYNA accumulates in astrocytes.

A second key-player in the metabolizing of 3-HK are monocytic cells infiltrating the CNS. They help astrocytes in the further metabolism to quinolinic acid (Guillemin et al., 2001). However, the low levels of sICAM-1 (ICAM-1 is the molecule that mainly mediates the penetration of monocytes and lymphocytes into the CNS) in the serum and in the CSF of non-medicated schizophrenic patients (Schwarz et al., 2000) and the increase of adhesion molecules during antipsychotic therapy indicate that the penetration of monocytes may be reduced in non-medicated schizophrenic patients (Müller et al., 1999).

36.9.2. The Glutamate System in Depression: Quinolinic Acid as a Depressogenic Substance

Apart from certain liver cells, only macrophage derived cells are able to convert tryptophan into quinolinic acid (Saito et al., 1993). Interestingly, in a model of infection, the highest concentrations of quinolinic acid are found in the gray and white matter of the cortex, not in subcortical areas. High levels of quinolinic acid therefore may lead to cortical dysfunction (Heyes et al., 1998).

The strong association between cortical quinolinic acid concentrations and local IDO activity supports the view that the induction of IDO is an important event in initiating the increase of quinolinic acid production (Heyes et al., 1992). In the CNS, invaded macrophages and microglial cells are able to produce quinolinic acid (Saito et al., 1993). Peripheral immune stimulation, however, under certain conditions also leads to increased CNS concentration of quinolinic acid (Saito et al., 1993). During a local inflammatory CNS process, the quinolinic acid production in the CNS increases without changes of the blood-levels of quinolinic acid. While the local quinolinic acid production correlates with the level of $\beta 2$ microglobulin, an inflammatory marker. Local CNS concentrations of quinolinic acid are able to far exceed the blood levels (Heyes et al., 1998).

A recent study showed that depressive symptoms are related to an increased ratio of KYN/KYNA in depression (Wichers et al., 2005). The increase of this ratio reflects that in depressed states KYN is preferentially metabolized to quinolinic acid—while the KYNA pathway is neglected. Therefore the preferred metabolism to quinolinic acid—but not the KYNA metabolism—is associated with more pronounced depressive symptoms.

An increase of quinolinic acid is strongly associated with several prominent features of depression: decrease in reaction time (Martin et al., 1992, 1993; Heyes et al., 1991) and cognitive deficits, in particular difficulties in learning (Heyes et al., 1998). In an animal model, an increase of quinolinic acid and 3-hydroxykynurenine was associated with anxiety (Lapin, 2003).

Accordingly, since the activity of the enzyme 3-OHase—directing to the production of quinolinic acid—is inhibited by type-2 cytokines but activated by proinflammatory type-1 cytokines (Alberati et al., 1996; Alberati and Cesura, 1998; Chiarugi et al., 2001), an increased production of quinolinic acid in depressive states would be expected.

The increased levels of quinolinic acid—as NMDA receptor agonist—lead to increased levels of glutamate. Quinolinic acid was shown to cause an overrelease of glutamate in the striatum and in the cortex, presumably by presynaptic mechanisms (Fedele and Foster 1993; Chen et al., 1999). The quinolinic pathway might be the mechanism involved in the increased glutamatergic neurotransmission in MD (Sanacora et al., 2004a).

Moreover, the plasma levels and expression in the brain of ICAM-1 seem to be related to depression: in patients treated with IFN- α , increased sICAM-1 levels were observed to be associated with increased depressive symptoms (Schäfer et al., 2004) and increased expression of ICAM-1 was found in the prefrontal cortex of elder depressive patients (Thomas et al., 2000). ICAM-1 is a type-1 related protein and a cell-adhesion molecule expressed on macrophages and lymphocytes. Increased expression of ICAM-1 is observed in inflammatory processes and promotes the influx of peripheral immune cells through the blood-brain barrier (Rieckmann et al., 1993). By this mechanism, macrophages and co-stimulatory lymphocytes can invade the CNS, further increasing the proinflammatory immune response. Moreover, inflammation is also associated with increased invasion of macrophages/microglia in the CNS (Lane et al., 1996) possibly further switching the balance of type-1/type-2 immune response in favour of type-1 including microglial activation. The alterations of the kynurenine pathway are summarized in Figure 36.2.

36.10. Prostaglandins in Schizophrenia and Depression

The role of PGE₂ in schizophrenia is not well studied; increased levels of PGE₂, however, have been described (Kaiya et al., 1989). PGE₂ induces the production of IL-6, which is consistently described to be increased in schizophrenia. Moreover, an increased COX-2 expression—which is stimulated by PGE₂—was found in schizophrenia (Das and Khan, 1998).

PGE₂ is a molecule of the proinflammatory cascade and stimulates the production of proinflammatory cytokines, e.g. IL-6, the expression of cyclooxygenase-2, and—as a cofactor—the expression of IDO. Therefore an increased secretion of PGE₂ would be expected in depressive disorders,

FIGURE 36.2. Alterations of the Kynurenine Metabolism in Schizophrenia and Major Depression Proinflammatory (Th1) cytokines are related to microglia activation, while antiinflammatory (Th2) cytokines are related to activation of astrocytes. Since astrocytes exhibit the kynurenic acid synthesising enzyme kynurenine aminotransferase (KAT), the production of this NMDA receptor antagonist may be induced during Th2 dominated immune response in schizophrenia. Microglia cells, on the other hand, exhibit indoleamine 2,3-dioxygenase (IDO) and kynurenine monooxygenase (KMO), the two key enzymes in the production of the NMDA receptor agonist quinolinic acid. Overproduction of quinolinic acid together with an increased cleavage of the indole ring of serotonin may be involved in the pathophysiology of major depression. (red arrows: mechanisms in schizophrenia; green arrows: mechanisms in depression; ↓ = activation; ⊥ = inhibition.)

too. Accordingly, in-vitro studies show an increased PGE_2 secretion from lymphocytes of depressed patients compared to healthy controls (Song et al., 1998). Increased concentrations of PGE_2 in saliva of depressed patients have been repeatedly described (Ohishi et al., 1988). Moreover, increased levels of PGE_2 have been observed, both in the cerebrospinal fluid and in the serum of depressed patients (Linnoila et al., 1983; Calabrese et al., 1986). As mentioned above, several antidepressants inhibit cytokine-induced PGE_2 production by inflammatory cells (Yaron et al., 1999).

36.11. The Role of the Hormones of the Hypothalamus-Hypophysis-Adrenal-Axis

As a product of activated monocytes and macrophages, IL-6 is one of the most frequently investigated immune parameters in patients suffering from major depression (MD). Most of the publications report a marked increase of in-vitro IL-6 production (Maes et al., 1993) or serum IL-6 levels in depressed patients (Maes et al., 1995a, 1997; Sluzewska et al., 1996; Berk et al., 1997; Frommberger et al., 1997; Song et al., 1998). Contradictory results are very few, indicating reduced (Katila et al., 1994), or not altered serum IL-6 levels (Brambilla and Maggioni, 1998). An age-related increase of IL-6 serum values was reported in patients with major depression (Ershler et al., 1993). The potential influence of possibly interfering variables, however, such as smoking, gender, recent infections and prior medication to IL-6 release and concentration must be considered (Haack et al., 1999).

Although IL-6 is not a type-1 cytokine, it may contribute to IDO activation by the stimulatory effect on PGE_2 , which acts as cofactor in the activation of IDO. This fits with a report on the correlation of increased IL-6 production in vitro with decreased tryptophan levels in depressed patients that emphasizes the influence of IL-6 on the serotonin metabolism in depressed patients (Maes et al., 1993).

There is no doubt that IL-6 is involved in the modulation of the HPA axis and increased availability of IL-6 in the hypothalamus is associated with increased HPA activity (Plata-Salaman, 1991). Activation of the HPA axis is one of the best-documented changes in major depression (Roy et al., 1987). Stress acts as a predisposing factor for MD, an increased susceptibility to stress has repeatedly been described in patients with MD, even prior to their first exacerbation of the disorder and psychosocial stressors frequently precede the onset of MD. Additionally, an altered HPA axis physiology and dysfunctions of the extrahypothalamic CRH system have been consistently found in subjects with MD (Hasler et al., 2004). Several studies demonstrate that MD patients exhibit higher baseline cortisol levels or at least much higher cortisol levels during the recovery period after psychological stress (Burke et al., 2005).

The effect of chronic stress on the peripheral immune system and its relevance for major depression has extensively been discussed (O'Brien et al., 2004). Recent in vivo evidence now suggests that stress-induced elevation of glucocorticoids also enhances immune function within the CNS through microglia activation and proliferation. Animal studies show that stress induces an enhanced expression of proinflammatory factors like IL-1 β (Pugh et al., 1999; Nguyen et al., 1998), macro-

phage migration inhibitory factor (MIF) (Bacher et al., 1998; Niino et al., 2000; Suzuki et al., 2000) and cyclooxygenase-2 (COX-2) (Madrigal et al., 2003) in the brain.

On the other hand, pro-inflammatory cytokines such as IL-1 and IL-6 are known to stimulate the HPA-axis via hypothalamic neurons. For example, the release of the CRH and GHRH is stimulated by IL-1 (Besedovsky et al., 1986; Berkenbosch et al., 1987), the central IL-1 upregulation leads to stimulation of CRH, the HPA-axis, and the sympathetic nervous system (Sundar et al., 1990; Weiss et al., 1994). Therefore, a vicious circle may be induced, if the stress response is not limited, as it is discussed in MD (see Figure 36.2).

Elevation of these proinflammatory factors is accompanied with dendritic atrophy and neuronal death within the hippocampus (Sapolsky, 1985; Woolley et al., 1990), which are also found in brains of subjects with MD (Campbell and Macqueen, 2004). These detrimental effects of glucocorticoids in the CNS are mediated by a rise in extracellular glutamate (Moghaddam et al., 1994; Stein-Behrens et al., 1994) and subsequent overstimulation of the NMDA receptor. Such an over-stimulation of the NMDA receptor results in excitotoxic neuronal damage (Takahashi et al., 2002). Nair and Bonneau could demonstrate that restraint-induced psychological stress stimulates proliferation of microglia, which was prevented by blockade of corticosterone synthesis, the glucocorticoid receptor, or the NMDA receptor (Nair and Bonneau, 2006). These data show that stress-induced microglia proliferation is mediated by corticosterone-induced, NMDA receptor-mediated activation within the CNS. Moreover, NMDA receptor activation during stress leads again to increased expression of COX-2 and PGE₂. Both, COX-2 and PGE₂ per se are able to stimulate microglia activation. On the other hand, the functional effects of IL-1 in the CNS—sickness behaviour being one of these effects—were also shown to be antagonized by treatment with a selective COX-2 inhibitor (Cao et al., 1999).

36.12. COX-2 Inhibitors in Schizophrenia and Depression

36.12.1. Cyclooxygenase-2 (COX-2) Inhibitors Inhibit the Production of Kynurenic Acid, Balance the Type-1/Type-2 Immune Response, and Have Therapeutic Effects in Early Stages of Schizophrenia

One class of modern drugs is well known to induce a shift from the type-1 to a type-2 dominated immune response: the selective cyclooxygenase-2 (COX-2) inhibitors. Several studies demonstrated the type-2 inducing effect of PGE₂—the major product of COX-2—while inhibition of COX-2 is accompanied by inhibition of type-2 cytokines and induction of type-1 cytokines (Pyeon et al., 2000; Stolina et al., 2000). Recently, PGE₂ has been shown to enhance the production of

type-2 cytokines such as IL-4, IL-5, IL-6, and IL-10; PGE₂ also drastically inhibits the production of the type-1 cytokines IFN- γ , IL-2, and IL-12 (Stolina et al., 2000). Therefore, inhibition of PGE₂ synthesis is hypothesized to be beneficial in the treatment of disorders with dysregulated T-helper cell responses (Harris et al., 2002). COX-2 inhibition seems to rebalance the type-1/type-2 immune response by inhibition of IL-6, PGE₂, and by stimulating the type-1 immune response (Litherland et al., 1999). Therefore COX-2 inhibition seems to be a promising approach in the therapy of schizophrenia, in particular since increased COX-2 expression was found in schizophrenia (Das and Khan, 1998).

COX-inhibition provokes differential effects on the kynurenine metabolism: while COX-1 inhibition increases the levels of KYNA, COX-2 inhibition decreases them (Schwieler et al., 2005). Therefore, psychotic symptoms and cognitive dysfunctions, observed during therapy with COX-1 inhibitors, were assigned to the COX-1 mediated increase of KYNA. The reduction of KYNA levels—by a prostaglandin-mediated mechanism—might be an additional mechanism to the above described immunological mechanism for therapeutic effects of selective COX-2 inhibitors in schizophrenia (Schwieler et al., 2005).

Indeed, in a prospective, randomized, double-blind study of therapy with the COX-2 inhibitor celecoxib add-on to risperidone in acute exacerbation of schizophrenia, a therapeutic effect of celecoxib was observed (Müller and Schwarz, 2002). Immunologically, an increase of the type-1 immune response was found in the celecoxib treatment group (Müller et al., 2004a). The clinical effect of COX-2 inhibition was especially pronounced regarding cognition in schizophrenia (Müller et al., 2005). The finding of a clinical advantage of COX-2 inhibition, however, could not be replicated in a second study. Further analysis of the data revealed that the outcome depends on the duration of the disease (Müller et al., 2004b). The efficacy of therapy with a COX-2 inhibitor seems most pronounced in the first years of the schizophrenic disease process. This observation is in accordance with results from animal studies showing that the effects of COX-2 inhibition on cytokines, hormones, and particularly on behavioural symptoms are dependent on the duration of the preceding changes and the time-point of application of the COX-2 inhibitor (Casolini et al., 2002). A point of no return for therapeutic effects regarding the pathological changes during an inflammatory process has to be postulated.

36.12.2. COX-2 Inhibition as a Possible Antiinflammatory Therapeutic Approach in Depression

Due to the increase of proinflammatory cytokines and PGE₂ in depressed patients, antiinflammatory treatment would be expected to show antidepressant effects also in depressed patients. In particular, COX-2 inhibitors seems to show advantageous results: animal studies show that COX-2 inhibition can

lower the increase of the pro-inflammatory cytokines IL-1 β , TNF- α , and of PGE₂, but it can also prevent clinical symptoms such as anxiety and cognitive decline, which are associated with this increase of pro-inflammatory cytokines (Casolini et al., 2002). Moreover, treatment with the COX-2 inhibitor celecoxib—but not with a COX-1 inhibitor—prevented the dysregulation of the HPA-axis, in particular the increase of cortisol, one of the biological key features associated with depression (Casolini et al., 2002; Hu et al., 2005). This effect can be expected because PGE₂ stimulates the HPA-axis in the CNS (Song and Leonard, 2000) and PGE₂ is inhibited by COX-2 inhibition. Moreover, the functional effects of IL-1 in the CNS—sickness behaviour being one of these effects—were also shown to be antagonized by treatment with a selective COX-2 inhibitor (Cao et al., 1999).

Additionally, COX-2 inhibitors influence—either directly or via CNS-immune mechanisms—the CNS serotonergic system. In a rat model, treatment with rofecoxib was followed by an increase of serotonin in the frontal and the temporo-parietal cortex (Sandrini et al., 2002). Since the lack of serotonin is one of the pinpoints in the pathophysiology of depression, a clinical antidepressant effect of COX-2 inhibitors would be expected due to this effect. A possible mechanism of the antidepressant action of COX-2 inhibitors is the inhibition of the release of IL-1 and IL-6. Moreover, COX-2 inhibitors also protect the CNS from effects of quinolinic acid (Salzberg-Brenhouse et al., 2003).

Accordingly, a clinical antidepressant effect of rofecoxib was found in 2,228 patients with osteoarthritis, 15% of them showing a co-morbid depressive syndrome, which was evaluated by a specific depression self-report. Co-morbid depression was a significant predictor for worse outcome regarding the osteoarthritis-related pain to rofecoxib therapy. Surprisingly, there was a significant decrease in the rate of substantive depression during therapy with 25 mg rofecoxib from 15% to 3% of the patients (Collantes-Esteves and Fernandez-Perrez, 2003).

Moreover, we were able to demonstrate a significant therapeutic effect of the COX-2 inhibitor on depressive symptoms in a randomized double blind pilot add-on study using the selective COX-2 inhibitor celecoxib in MD (Müller et al., 2006). Although those preliminary data have to be interpreted cautiously and intense research has to be provided in order to evaluate further the therapeutic effects of COX-2 inhibitors in MD, those results are encouraging for further studies dealing with the inflammatory hypothesis of depression with regard to pathogenesis, course and therapy.

Summary

In schizophrenia and depression, opposite patterns of type-1 – type-2 immune activation seem to be associated with differences in the IDO activation and in the tryptophan—kynurenine metabolism resulting in increased production of kynurenine acid

in schizophrenia and of increased quinolinic acid in depression. These differences are associated with an imbalance in the glutamatergic neurotransmission, which may contribute to an overweight of NMDA agonism in depression and of NMDA antagonism in schizophrenia. The differential activation of microglia cells and astrocytes may be an additional mechanism contributing to this imbalance. The immunological imbalance results both in schizophrenia and in depression in an increased PGE₂ production and probably also in an increased COX-2 expression. Although there is strong evidence for the view, that the interactions of the immune system, IDO and the serotonergic system, and glutamatergic neurotransmission play a key role in schizophrenia and in depression, several gaps, e.g. the roles of genetics, disease course, sex, different psychopathological states, etc. have to be bridged by intense further research. Moreover, COX-2 inhibition is only one example for possible therapeutic mechanisms acting on these mechanisms. Also the effects of COX-2 inhibition in the CNS as well as the different components of the inflammatory system, the kynurenine-metabolism and the glutamatergic neurotransmission need careful further scientific evaluation.

Review Questions/Problems

1. The NMDA hypothesis of schizophrenia refers to the following neurotransmitter disturbance:

- a. mesolimbic hyperactivity of dopamine
- b. tuberoinfundibular inhibition of prolactin release by dopamine
- c. hypofunction of the glutamatergic cortico-striatal pathway
- d. mesolimbic hyperactivity of glutamate
- e. all of the above

2. The so far only known endogenous NMDA receptor antagonist is:

- a. glutamate
- b. glycine
- c. ketamine
- d. kynurenic acid
- e. quinolinic acid

3. The proposed neurotransmitter imbalance in major depression is best characterized by:

- a. increased serotonin, increased glutamate, reduced norepinephrine
- b. increased serotonin, increased norepinephrine, reduced glutamate
- c. increased glutamate, decreased serotonin, decreased norepinephrine
- d. none of the above

4. The best replicated immune findings in schizophrenia are:

- a. increased in vitro production of IL-2 and decreased serum levels of IL-6
- b. decreased in vitro production of IL-2 and IFN- γ and decreased serum levels of IL-6
- c. decreased in vitro production of IL-2 and IFN- γ and increased serum levels of IL-6
- d. increased serum levels of IL-2 and IFN- γ and decreased in vitro production of IL-6
- e. none of the above

5. The following immune response can be frequently detected in depressed patients:

- a. an allergy-like Th2 predominance with increased levels of IgE in nearly all depressed patients
- b. a decreased Th1 activation in melancholic patients and an increased Th1 activation in non-melancholic depressed patients
- c. an increased activation of the adaptive immune system in melancholic patients and an increased activation of the specific immune system in non-melancholic patients
- d. an increased Th1 activation in melancholic patients and a decreased Th1 activation in non-melancholic depressed patients

6. The most common psychiatric side effect of IFN- α administration is:

- a. paranoid ideation
- b. optical and—less frequent—acoustic hallucinations
- c. manic episodes
- d. depression
- e. tics

7. IFN- α administration induces the degradation of the amino acid:

- a. choline
- b. cysteine
- c. serine
- d. tryptophan
- e. tyrosine

8. The typical immunological effect of antidepressant drugs is:

- a. induction of a more specific immune response
- b. inhibition of B cell proliferation and antibody production
- c. downregulation of Th1 cytokine production
- d. downregulation of Th2 cytokine production
- e. upregulation of Th1 cytokine production

9. The following enzymes of the kynurenine pathway are induced by pro-inflammatory cytokines such as IFN- γ and TNF- α :

- a. tryptophan 2,3 dioxygenase, indoleamine 2,3-dioxygenase, kynurenine monooxygenase

- b. indoleamine 2,3-dioxygenase, kynurenine hydroxylase (monooxygenase), kynurenine aminotransferase
- c. indoleamine 2,3-dioxygenase, kynurenine hydroxylase (monooxygenase)
- d. tryptophan 2,3 dioxygenase, kynurenine hydroxylase (monooxygenase)
- e. only indoleamine 2,3-dioxygenase

10. The limiting step in serotonin synthesis is in all probability:

- a. tryptophan availability
- b. serotonin availability in a negative feed back
- c. tryptophan hydroxylase activity
- d. a and c
- e. b and c

11. Glucocorticoids:

- a. induce central nervous production of pro-inflammatory mediators
- b. inhibit central nervous production of pro-inflammatory mediators
- c. induce glutamate signal at the NMDA receptor
- d. inhibit glutamate signal at the NMDA receptor
- e. a and c
- f. b and d
- g. b and c

12. Astrocytes are:

- a. immunologically 'silent' glial cells
- b. responsible for a Th1-like immune response within the CNS
- c. part of the nerve sheath within the brain
- d. responsible for a Th2-like immune response within the CNS
- e. not involved in neurotransmitter reuptake and metabolism

13. Proinflammatory cytokines:

- a. stimulate the HPA axis
- b. have no effect on the HPA axis
- c. induce dendritic atrophy
- d. none of the above
- e. a and c
- f. b and c

14. Inhibition of cyclooxygenase isoforms has the following effects:

- a. COX-1 inhibition increases the levels of kynurenic acid
- b. COX-2 inhibition decreases the levels of kynurenic acid
- c. COX-2 inhibition induces a Th1 shift under non-inflammatory conditions
- d. all of the above
- e. b and c

15. Administration of the COX-2 inhibitor celecoxib was shown to:

- induce exacerbation of psychotic symptoms in schizophrenia
- improve psychotic and especially cognitive in schizophrenia
- be more efficient in chronic schizophrenia than in the early stages
- enhance antidepressant therapy when added to a conventional antidepressant drug
- a and c
- b and d

Drugs of Abuse and the Immune System

Toby K. Eisenstein, David E. Kaminsky, Rahil T. Rahim, and Thomas J. Rogers

Keywords Cannabinoids; Chemokines; Cocaine; Cytokines; Immunosuppression; Morphine; Opioids; T-helper 1/T-helper 2 (Th1/Th2); Δ^9 -tetrahydrocannabinol (Δ^9 -THC); Tolerance; Withdrawal

37.1. Introduction

It has been clearly demonstrated that opioids, cannabinoids, and cocaine alter a variety of assays of immune function when added to cells of the immune system in vitro. Receptors and/or mRNA for the receptors for opioids and cannabinoids have been demonstrated in a variety of cells of the immune system. In many cases, especially for the opioids, pharmacological specificity of the action of the drugs has been verified using appropriate antagonists. These observations provide a biological basis for concluding that drugs of abuse have direct effects on immune cells. In addition, all three drugs alter immune responses of rodents, and in some cases, humans, when treated in vivo. In vivo mechanisms of action may be harder to determine as the drugs may activate other physiologic systems in the body that may also impinge on immune responsiveness, such as the HPA and the SNS. Nonetheless, drug abusers suffer the cumulative effects of direct and indirect effects of the drugs on the immune system. Assays of immune function that have been measured include effects on the innate immune system, which encompass effects on macrophages and NK cells, and effects on adaptive immunity, which include the humoral and cellular arms of the immune system. Considerable attention has been focused on cytokine and chemokine mediators of immune function that are modulated by the drugs and on their capacity to modulate activation of the various arms of the immune system by polarization of the cytokine profile. Other commonly used and abused drugs include nicotine and alcohol, both of which have marked effects on the immune system, and are frequently part of the panoply of artificial substances used by addicts. In addition, methamphetamines can alter immune status. Due to space limitations the reader is referred

to key papers on these subjects (Sopori, 2002; Gamble et al., 2006; Pacifici et al., 2002)

37.2. Fundamental Concepts

37.2.1. Opioid and Cannabinoid Receptors are on Cells of the Immune System

37.2.1.1. Opioid Receptors

There is now indisputable evidence of natural physiological connections between the neural and immune systems. Much of the evidence supporting this link has come from studies of opioids and cannabinoids and their effects on immune responses. Opioid receptors were first demonstrated biochemically in brain in the early 1970s. Three distinct receptors were discovered in neural tissue and were designated mu, kappa, and delta (Simon, 1991). Their respective natural ligands were found to be the neuropeptides, β -endorphin (predominantly mu), dynorphin (kappa) and methionine-enkephalin (delta) (Akil et al., 1984), although there is considerable cross-reactivity. Alkaloid opioids, including morphine and heroin, bind primarily, but not exclusively, to the mu receptor. Morphine is extracted from opium produced by the poppy plant, and heroin is synthetically diacetylated morphine. In vivo, the major metabolite of heroin is morphine. Most laboratory studies employ morphine because it is less lipophilic than heroin, is used therapeutically, and is easier to dissolve. Since the mu receptor is the major target of both compounds, results obtained with morphine are believed to be directly translatable to heroin abuse, although there is some evidence for unique biologically active heroin metabolites (Rossi et al., 1996).

Credit for recognition of the potential existence of receptors for opioids on cells of the immune system is given to Joseph Wybran in the laboratory of Govaerts. In 1979 he reported modulation of the function of human T cells, purified from normal peripheral blood, by exogenous and

endogenous opioids (Wybran et al., 1979). He observed that if morphine was added to human T cells in culture, they lost the ability to rosette with sheep red blood cells (SRBCs), a fortuitous property that was used before flow cytometry to enumerate T cells. In contrast, when the opioid neuropeptide, met-enkephalin, was added to the T cells, rosetting increased. The actions of both opioids were blocked by naloxone, an antagonist for all types of opioid receptors, showing pharmacological specificity of the effects. Wybran proposed that, "normal human blood T lymphocytes bear surface receptor-like structures for morphine and methionine-enkephalin." He concluded that, "Such findings may provide a link between the central nervous system and the immune system." This paper was seminal because it presented strong pharmacologic data to support the existence of opioid receptors on cells of the immune system. However, it has been very difficult to demonstrate opioid receptors routinely by binding studies using cells of the immune system, although scattered reports of positive results are published (Sibinga and Goldstein, 1988; Sharp et al., 1998). The difficulties may be due to low receptor numbers on cells of the immune system, to inability to obtain enough purified subsets of immune cells to do adequate binding studies, or to a need to activate immune cells before the receptors are expressed. With the advent of cloning of the opioid receptors from brain tissue, mRNA transcripts have been detected in primary cells of the immune system or lymphoid or monocytic cell lines for all three classes of opioid receptors (Loh and Smith, 1990; McCarthy et al., 2001; Sharp et al., 1998).

37.2.1.2. *Cannabinoid Receptors*

Cannabinoid receptors were identified and cloned several years after the opioid receptors. Cannabinoids, like the psychotropic active ingredient extracted from marijuana, Δ^9 -tetrahydrocannabinol (Δ^9 -THC), were initially believed by some to simply interdigitate into cell membranes. Subsequently, a cannabinoid receptor was cloned from neural tissue (Zhu et al., 1993). When lymphoid tissue was probed for cannabinoid receptor transcripts, a second receptor (designated CB2) was discovered that is primarily expressed in the immune system and has 44% homology to the first receptor (designated CB1) (Munro et al., 1993). mRNA for CB2 is expressed by Natural Killer (NK) cells, B cells, T cells and macrophages (Lee et al., 2001), and radiolabeled cannabinoids have been shown to bind to mouse spleen cells and human T cell lines (Kaminski et al., 1992; Schatz et al., 1997). Endogenous cannabinoid ligands have also been discovered, but they are not peptides like the opioids. Anandamide, or arachidonylethanolamide, is a polyunsaturated N-acylethanolamine (Devane et al., 1992), as is 2-arachidonoyl-glycerol (Mechoulam et al., 1995; Di Marzo and Deutsch, 1998). It should be appreciated that the cannabinoids may exert their effects by both receptor-dependent and -independent mechanisms.

37.2.2. Mechanisms by Which Drugs of Abuse Can Affect Cells of the Immune System

Testing of whether drugs of abuse can alter immune function has been carried out by in vivo administration of the drug, with assessment of in vivo or ex vivo immune function, or alternatively, by harvesting immune cells from a drug naïve (normal) host and exposing them to the drug in vitro. If a drug is given in vivo, there is the possibility that effects on the immune system are not due to a direct interaction of the drug with cells of the immune system, but that immunomodulatory effects are instead mediated by additional systems in the body. For example, opioids, cannabinoids, and other drugs of abuse, can modulate the Hypothalamic-Pituitary-Adrenal (HPA) axis, which can lead to release of immunosuppressive corticosteroids or to activation of the sympathetic nervous (SNS) system, resulting in downstream alterations in immune function. Effects on immune function could thus be a combination of indirect and direct effects if the drug is given in vivo.

An additional and important consideration is that both the neural system and cells of the immune system produce opioid peptides, which could lead to complicated interacting pathways, especially in vivo (Carr, 1991). In evaluating the studies discussed in this Chapter, it should be recognized that most immune responses were assessed two to three hours after a single injection of a drug. For studies testing longer exposure to morphine, the drug is frequently delivered by subcutaneous implantation of a pellet that slowly releases the drug over a period of a week. Alternatively, mini-pumps dispensing drugs can be implanted. In the case of morphine or other addictive opioids, these methods are used to avoid episodes of withdrawal, which has its own immunomodulatory effects on immune function. In fact, a complication of studies with opioids is that repeated administration can result in tolerance to their analgesic effects, and in many, but not all, cases tolerance to the effects of the drugs on the immune system (Eisenstein et al., 2006). There are a limited number of studies that have addressed the effects of tolerance and of withdrawal from morphine on immune responses (Eisenstein et al., 2006).

37.3. Functional Consequences of Drugs of Abuse on the Immune System

37.3.1. Effects on Innate Immunity and the Inflammatory Response

37.3.1.1. *Cells and Molecules of the Innate Immune Response*

It is well established that drugs of abuse are involved in a wide range of immunomodulatory activities. Among the areas in immune system function in which these alterations have been observed is innate immunity. This arm of the immune system does not exhibit specificity in recognizing foreign pathogens. It encompasses NK cells and the "professional" phagocytic

cells that are the first responders to inflammation or infection. Natural Killer cells are lymphocytes that are involved in recognition and killing of mammalian cells that express foreign antigens, such as tumor antigens or viral antigens. They also produce cytokines (small proteins produced by immune cells that act in an autocrine, paracrine, or endocrine fashion) that can activate the mononuclear phagocytic cells. The phagocytic cells engulf microbes invading the host and include polymorphonuclear (PMN) leukocytes (also called neutrophils), monocytes, and macrophages. Monocytes are formed in the bone marrow and released into the peripheral blood. They are mature, but unactivated cells. When they are stimulated in various ways they can develop into macrophages in vivo or in vitro. Macrophages have several states of activation that are characterized by their production of cytokines and by their levels of microbicidal compounds, including reactive oxygen intermediates (ROIs) and reactive nitrogen intermediates. Macrophages also play an important role in the acquisition and presentation of foreign antigens to lymphocytes, which triggers the adaptive immune response.

37.3.1.2. *Effects of Opioids, Cannabinoids, and Cocaine on NK Cells*

In the cellular repertoire of the innate immune system, NK cells have the unique ability to kill infected target cells in a manner independent of antigen recognition. Alteration in NK cell function was among the earliest, and has been one of the most consistently observed, effects of drugs on the immune system. Many studies have shown that administration of opioids to rodents results in the suppression of NK cell activity. Leibeskind's laboratory (Shavit et al., 1986b) was the first to show that morphine given to rats subcutaneously for 4 days suppressed NK cell activity. They later concluded that this effect was not directly on the NK cells in the periphery, because N-methylmorphine, which does not pass the blood-brain barrier, did not depress NK function (Shavit et al., 1986a). Subsequently, Weber and Pert (1989) reported that injection of morphine into the periaqueductal gray (PAG) region of the brains of rats resulted in suppression of NK cell activity in the spleens of these animals 3 hr later. Morphine administered into 5 other brain sites was without effect. Moreover, the opioid specific antagonist, naltrexone, blocked the effects in the studies by both groups, implicating the involvement of classic opioid receptors in modulating NK cell activity. Studies have also been carried out in which morphine has been given to normal human subjects under controlled conditions. The results show that peripheral blood NK cell activity is depressed 24 hr after morphine administration (Yeager et al., 1995). The exact mechanism by which engagement of opioid receptors in certain regions of the brain alters peripheral functional capacity of NK cells is not known. However, more recent work implicates a neural pathway involving dopamine in modulating NK activity (Saurer et al., 2006). Nonetheless, the mu opioid receptor (MOR) is certainly involved in the effects on NK cell activity, as mice with a genetic deletion

of MOR do not respond to morphine with depressed NK cell activity (Gavériaux-Ruff et al., 1998).

The cannabinoids represent another class of abused drugs affecting immune cell function. Although fewer studies have explored the effects of cannabinoids on NK cells, the literature to date shows that the activity of splenic NK cells is suppressed following in vivo injection of Δ^9 -THC into rats and mice (Patel et al., 1985; Klein et al., 1987), and also after in vitro treatment of human peripheral blood NK cells (Specter et al., 1986). Δ^9 -THC has also been shown to block proliferation of NK cells in response to the cytokine, IL-2, by down-regulating the IL-2 receptor (Zhu et al., 1993).

There are a limited number of reports of immunomodulation by cocaine. In vivo administration of cocaine i.v. to humans elevated NK cell activity in peripheral blood, but exposure of leukocytes to the drug in vitro had no effect (Van Dyke et al., 1986). It was hypothesized that the in vivo effects occurred via release of epinephrine from the SNS (Van Dyke et al., 1986). Contradictory results have been reported for the effect of cocaine on NK activity in rats, with no effect in vivo (Bayer et al., 1996) or suppression of activity after acute or chronic in vivo administration (Pacifici et al., 2003).

37.3.1.3. *Drugs of Abuse Alter Functions of PMN Leukocytes and Monocytes/Macrophages*

Opioids given in vivo have been demonstrated to inhibit ex vivo phagocytic cell activity (Tubaro et al., 1983). Opioids selective for all three classes of opioid receptors (mu, kappa, and delta), when added to mouse peritoneal macrophages in vitro, inhibited phagocytosis of the yeast *Candida albicans*, and the effects were blocked by the respective receptor selective antagonists (Szabo et al., 1993). Morphine given in vivo by slow release pellet, or when added to murine bone marrow cells in vitro, blocked the maturation of precursor cells into macrophage colonies (Roy et al., 1991). Morphine pellets also inhibit adhesion of leukocytes to vascular endothelium, thus reducing inflammation (Ni et al., 2000). Studies have also been carried out in which morphine has been added to human peripheral blood mononuclear cells (PBMCs), a semi-purified cell fraction that includes lymphocytes and monocytes. Further work has shown the morphine also inhibits the ability of phagocytic cells to produce superoxide and peroxide (Peterson et al., 1987a). Peterson and colleagues (Chao et al., 1992) have shown that the inhibitory effects of this opioid on phagocytic cell activity are due, at least in part, to the production of Transforming Growth Factor (TGF)- β . Reactive oxygen intermediates, such as superoxide, contribute to the microbicidal activity of phagocytes, so impairment of their production would be consonant with reduced capacity to kill ingested yeast or other microbes. Macrophages taken from mice exposed to morphine can undergo apoptosis (Nair et al., 1997), and evidence supports a role of ROI and nitric oxide (NO) in this process (Singhal et al., 1998; Bhat et al., 2004). Usually depression of NO is associated with decreased macrophage function, so these findings are dichotomous with the other evidence on effects of opioids on these cells.

Δ^9 -THC is also reported to decrease the phagocytic activity of human peripheral blood monocytes and mouse peritoneal macrophages (Specter et al., 1991; Lopez-Cepero et al., 1986). Alveolar macrophages of marijuana smokers exhibited decreased microbicidal activity against *Staphylococcus aureus*, which is associated with decreased production of NO (Roth et al., 2004). Δ^9 -THC also affects macrophage processing of exogenous protein antigens through the CB2 receptor, as shown pharmacologically and using CB2-deficient mice (McCoy et al., 1999; Buckley et al., 2000).

Cocaine, like Δ^9 -THC and morphine, has been reported to decrease the antimicrobial activity of alveolar macrophages obtained from chronic crack cocaine smokers (Roth et al., 2004) and to decrease parameters of mouse macrophage activation (Ou et al., 1989; Pacifici et al., 1993). However, in contrast to the effects of opioids, cocaine has been shown to increase the activation of PMNs in human subjects, as evidenced by increased killing of *Staphylococcus aureus* (Baldwin et al., 1997).

37.3.1.4. Effects of Drugs of Abuse on the Production of Cytokines and Chemokines

One mechanism by which drugs of abuse modulate immune function is through effects on expression of cytokines and chemokines, or on the functional capacity of their receptors. These proteins act as messengers to direct appropriate cellular activation and differentiation (cytokines) and coordinate the migration of cells to particular sites of inflammation or infection (chemokines). Cytokines have a number of functions. They may alter the innate immune response, act as a bridge to influence the type of adaptive immune response, and can also amplify adaptive immune responses. Chemokines can participate in innate immunity, and also influence adaptive immunity by orchestrating the type of cells that migrate to a pathological site. In addition, some of the chemokines can act as co-activators of immune cell function. Proinflammatory and anti-inflammatory cytokines, and also chemokines, which are part of the innate immune response, mediate generalized symptoms of inflammation including fever (IL-1), organ damage (tumor necrosis factor (TNF)- α), and migration of phagocytic cells (IL-8, CCL2), or dampen these responses (IL-10). Cytokines like IL-5 drive B cell maturation and antibody production.

Morphine and other ligands for the mu receptor have been shown to modulate production of both cytokines and chemokines, although the results have been complex. For example, treatment of stimulated PBMCs with morphine decreased IFN- γ production (Peterson et al., 1987b), but increased TGF- β expression (Chao et al., 1992). As TGF- β can be immunosuppressive, the relationship between the levels of the two cytokines may be causal. A biphasic dose response relationship was shown for release of proinflammatory cytokines from stimulated mouse peritoneal macrophages treated with morphine in vitro, with low doses increasing release of IL-6 and

TNF- α , and high doses inhibiting them (Roy et al., 1998a). In contrast, when mice were treated with relatively high doses of morphine in vivo and their peritoneal macrophages were stimulated ex vivo, they showed increased production of IL-12 and TNF- α (Peng et al., 2000).

The pattern of proinflammatory cytokines produced has implications for the character of the adaptive immune response, which will occur if the host is exposed to a foreign antigen. A T-helper type 1 (Th1) cytokine profile polarizes the immune response towards a cellular immune response, whereas a T-helper type 2 (Th2) profile favors antibody responses (Mosmann and Coffman, 1987). IFN- γ is a marker of a Th1 response, and IL-4 is indicative of a Th2 response. There is evidence that morphine given in vivo biases the immune response toward a Th2 response (Roy et al., 2004). The consequences of this apparent shift toward Th2-type immunity are not clear, since other studies show that antibody production is suppressed in animals treated similarly with morphine (Bussiere et al., 1993). These results will be discussed in greater detail below.

In regard to chemokines, exposure of PBMCs to DAMGO, a synthetic peptide selective for the mu-opioid receptor, has been shown to increase the expression of pro-inflammatory chemokines CCL2, CCL5, and CXCL10 (Wetzel et al., 2000), and the chemokine receptors CXCR4 and CCR5, the major Human Immunodeficiency Virus (HIV)-1 co-receptors (Steele et al., 2003; Choi et al., 1999), the latter leading to increased replication of HIV. Another major and important finding concerning opioids and chemokines is that there is heterologous desensitization between selective opioid and chemokine receptors (Adler and Rogers, 2005). Both classes of receptors are G protein-coupled. Engagement of one of the receptors leads to failure of the other receptor to signal, probably through transphosphorylation of the second receptor (Steele et al., 2002; Szabo et al., 2002; Szabo et al., 2003; Chen et al., 2004). Prior treatment of rats with CCL5 or CXCL12 into the PAG region of the brain, blocks the antinociceptive effects of morphine similarly administered (Szabo et al., 2002). Heterologous desensitization of chemokine receptors by opioids blocks chemotaxis of human PBMCs to CXCL12 (Szabo et al., 2002; Grimm et al., 1998) and also blocks HIV infection of primary human monocytes in vitro (Szabo et al., 2003). (Figure 37.1)

There are striking parallels between the effects of opioids and cannabinoids on cytokine production. Δ^9 -THC has also been shown to suppress proinflammatory cytokines crucial in host defense, such as TNF- α (Fischer-Stenger et al., 1993). Further studies showed a biphasic dose response to cytokine production by Δ^9 -THC on human PBMCs, but it was the opposite of that observed with morphine, with low doses inhibiting TNF- α , IL-6 and IL-8, and high doses increasing these cytokines (Berdyshev et al., 1997). In a mouse model of Legionnaires' Disease, Δ^9 -THC blocked IFN- γ , IL-12, and IL-12 receptor expression and increased IL-4 levels, reflecting a polarization of the immune response towards a Th2 phenotype (Perez-Castrillon et al., 1992; Klein and Cabral, 2006). Similar

Opioid-Induced Heterologous Desensitization of CCR5

FIGURE 37.1. Heterologous desensitization of chemokine receptors following activation of the MOR. The activation of MOR by either morphine or a MOR-selective agonist such as DAMGO leads to the induction of a cross-desensitization pathway which rapidly leads to the inactivation of some of the chemokine receptors, including CCR5. At this point the cell is unresponsive to CCR5-selective chemokines such as CCL3, 4 or 5. However, the MOR-induced cross-desensitization does not effect all chemokine receptors. For example, CXCR4 remains fully responsive to activation by the CXCR4-specific chemokine CXCL12. The cell is also protected from infection with an R5 strain, but not an X4 strain, of HIV-1.

results were obtained using Δ^9 -THC on activated human T cells (Yuan et al., 2002). Like morphine, cannabinoids have also been shown to increase the mRNA for the chemokines CCL2, and also for IL-8, in a monocytic cell line transfected with the CB2 receptor (Jbilo et al., 1999).

Cocaine is also reported to modulate the production of cytokines and chemokines. Analysis of *in vitro* cocaine treatment on cytokine and chemokine expression by mouse and human cells has revealed a decreased ability of stimulated immune cells to produce INF- γ , TNF- α , IL-1, and IL-8 (Watzl et al., 1992; Shen et al., 1994). Other studies did not agree, and reported an increase in TNF- α , IL-8, IL-2 and other chemokines (Zhang et al., 1998; Wang et al., 1994). Interestingly, *in vivo* infusion of cocaine showed an increase in INF- γ and a decrease in the anti-inflammatory cytokine, IL-10 (Gan et al., 1998). The lack of concordance between *in vitro* and *in vivo* studies again suggests that drugs may have complex effects *in vivo*, partly because they can engage mediators from other systems that might affect immune function.

37.3.2. Effects on Adaptive Immunity

37.3.2.1. Humoral Immunity (Antibody Responses)

Morphine given by slow-release pellet has been shown to block the capacity of mouse spleen cells to mount an *ex vivo* antibody response to the artificial antigen, SRBCs, and a naltrexone releasing pellet blocks the effect of the opioid (Bussiere et al., 1992). Serum antibody responses to

tetanus toxoid (Eisenstein et al., 1990) and to trinitrophenylated bovine serum albumin (Weber et al., 1987) were also suppressed in mice by morphine given *in vivo*. Morphine, U50,488H (kappa agonist) and deltorphin II (delta₂ agonist) have all been shown to be immunosuppressive when administered by osmotic mini-pump. All three agonists gave inverted U-shaped dose response curves over a dose range of 0.1 to 10 mg/kg/day, with maximal immunosuppression between 0.5 and 2 mg/kg/day (Rahim et al., 2001). It has been suggested that part of the suppressive effect of morphine pellets on humoral immune responses is due to activation of the HPA-axis (Pruett et al., 1992). However, all of the effects of opioids on the capacity to mount an antibody response cannot be mediated, since spleen cells taken from normal animals that were never exposed to opioids *in vivo*, have depressed capacity to make antibodies to SRBCs when treated with various opioid agonists *in vitro*, (Taub et al., 1991; Eisenstein et al., 1995). Also, quaternary naloxone, which does not pass the blood-brain barrier, blocks the immunosuppressive effect of a kappa agonist given *in vivo* (Radulovic et al., 1995), suggesting that the drug is acting in the periphery. The suppressive effects of morphine and U50,488H *in vivo* and *in vitro* appear to result from individual effects on T cells and macrophages (Bussiere et al., 1993; Guan et al., 1994) which are needed to cooperate with B-cells to generate antibody production. Morphine has also been shown to have an effect on the mucosal antibody response. Cultured ileal segments from mice receiving morphine and given cholera toxin orally were suppressed in their ability to produce IgA specific for cholera toxin compared with mice receiving placebo (Peng et al., 2001). The effect of chronic administration of morphine and withdrawal from the drug have been examined for effects on responses to a B-cell mitogen (LPS) (Bryant et al., 1987) and on antibody responses (Rahim et al., 2002). Exposure to morphine from slow-release pellets for 3 to 4 days led to tolerance to the immunosuppressive effects in both assays, and withdrawal led to renewed immunosuppression. Extensive investigation into the mechanisms of withdrawal-induced immunosuppression showed that there was a deficit of macrophage function (Rahim et al., 2003; Rahim et al., 2005). In contrast, other data suggest that withdrawal biases the immune response to a Th2 cytokine phenotype (Kelschenbach et al., 2005). At present it is not known how to reconcile these observations.

Δ^9 -THC, like morphine, has been shown to suppress *in vitro* antibody formation by mouse spleen cells (Kaminski et al., 1992; Kaminski et al., 1994). Interestingly, Δ^9 -THC is reported to increase IgG1 responses to *Legionella pneumophila* in drug-treated animals, presumably by polarizing the immune response towards a Th2 phenotype (see below under T cell responses) (Newton et al., 1994).

Cocaine has been investigated for capacity to alter antibody responses and has been found to be immunosuppressive for some antigens, but not others (Ou et al., 1989; Watson et al., 1983; Havas et al., 1987).

37.3.2.2. T Cell Responses

Morphine given by slow-release pellet also inhibits the ability of splenic T-cells to respond to mitogens (plant products that cause nonspecific proliferation of immune cells). Thus, at 72 hr after pellet implantation splenic murine T cells had a marked inhibition of replication when exposed to Concanavalin A (Con A) (Bryant et al., 1987). Reduction in response to Con A has also been observed using peripheral blood T cells of rats two hours after a single subcutaneous injection of morphine (Bayer et al., 1990). Morphine has also been reported to inhibit thymocyte and lymph node derived T cell proliferation when added to the cells in vitro (Roy et al., 1997; Wang et al., 2001). Other measures of T cell function relate to adaptive immunity in the cellular arm of the immune system. Several studies have shown that chronic morphine exposure inhibits development of delayed-type hypersensitivity (DTH) in rats, mice, and pigs (Pellis et al., 1986; Bryant and Roubesh, 1990; Molitor et al., 1992), and cytotoxic T cells in mice (Carpenter and Carr, 1995).

Δ^9 -THC has also been shown to inhibit responses to Con A in a protocol which exposed mouse spleen cells in vitro to the drug (Klein et al., 1985). Cannabinoids have been studied for their ability to polarize T cells toward Th1 or Th2 responses. It has been reported that Δ^9 -THC given to mice that are subsequently infected with *Legionella pneumophila* suppressed IL-12R β 2 expression by a CB1 mediated mechanism and increased GATA3 mRNA via CB2 signaling (Klein et al., 2004). The IL-12 receptor participates in Th1 responses and GATA3 biases towards a Th2 response, leading to the conclusion that cannabinoids can polarize T cell responses towards a Th2 phenotype. Evidence from exposure of activated human peripheral blood T cells to Δ^9 -THC also supports a Th2 polarization (Yuan et al., 2002). Δ^9 -THC has also been shown to suppress cytotoxic T cell activity against both allogeneic cells (Klein et al., 1991) and virus-infected cells (Fischer-Stenger et al., 1992).

An acute i.v. dose of cocaine has been reported to have an effect similar to that of morphine in suppressing proliferation of T cells in the peripheral blood of rats exposed to Con A two hours after injection of the drug (Bayer et al., 1996). Cocaine has been shown to inhibit production of Th2 cytokines, which would be expected to reduce antibody responses (Wang et al., 1994). Cocaine given orally also suppressed DTH responses in mice (Watson et al., 1983).

37.4. Effects of Drugs of Abuse on Infection

37.4.1. Overview

The majority of publications cited above concluded that the various drugs of abuse were immunosuppressive. A logical conclusion from these observations would be that exposure to

the drugs would sensitize to infection. Clinical observations of intravenous drug using (IVDU) populations have noted an increased incidence of bacterial infections (Risdaal et al., 1996). However, it has not been possible to determine whether more infection occurs in this group because of unsanitary use of needles or because the drugs render the person more susceptible. This question has become important in regard to HIV infection, since in the United States one third of all cases of HIV occur in IVDUs (CDC, 2000). Epidemiologic studies have been compromised because drug abusers usually abuse more than one drug, and also smoke and abuse alcohol. Studies have not adequately teased apart these factors, nor controlled for drug dosage or frequency of drug use. Several other reviews explore these issues in depth (Kapadia et al., 2005; Rogers et al., 2005). Laboratory studies using animal models of infections can more definitively clarify whether drugs of abuse can be cofactors in susceptibility to infection. Yet, surprisingly there are only a few studies on drugs of abuse and experimental infections of any type.

37.4.2. Effects of Drugs of Abuse on Infections Other than HIV

Morphine has been shown to sensitize mice to fungal (*Candida albicans*) (Tubaro et al., 1983), parasitic (*Toxoplasma gondii*) (Chao et al., 1990), and bacterial (*Salmonella typhimurium*, *Streptococcus pneumoniae*) infections (MacFarlane et al., 2000; Wang et al., 2005). Further, morphine and withdrawal from morphine are reported to induce sepsis and enhance sensitivity to bacterial LPS (Hilburger et al., 1997; Roy et al., 1998b), as well as sensitize to *Salmonella* infection (Feng et al., 2005). Δ^9 -THC is reported to sensitize to the bacteria, *Legionella pneumophila* and *Listeria monocytogenes* (Newton et al., 1994; Morahan et al., 1979), and to herpes simplex virus (Cabral et al., 1986).

37.4.3. Effects of Drugs of Abuse on HIV or Related Infections

There are several papers showing that opioids up-regulate HIV replication when added to infected human peripheral blood cells or microglia in vitro (Peterson et al., 1990, 1994; Li et al., 2002). As mentioned in Section 37.2.1.4 on cytokines and chemokines, the effects of opioids on HIV infection may be related to drug-induced alterations in cytokine or chemokine production or in expression of chemokine receptors (Peterson et al., 1994; Li et al., 2002; Steele et al., 2003). Proinflammatory cytokines, particularly TNF- α , can activate T cells and lead to increased HIV replication, and chemokine receptors are co-receptors for the virus. It is to be expected that modulation of chemokine and/or chemokine receptor levels can alter HIV infectivity through increasing the pool of infectable cells or by altering availability of the number of co-receptors.

Similar immunodeficiency syndromes may result in monkeys and cats infected with simian immunodeficiency virus

(SIV) and feline immunodeficiency virus (FIV), respectively, but studies with these viruses have not provided a clear indication of the influence of opioids on the development of these immunodeficiency diseases. In one study, monkeys maintained on morphine had a slower progression of SIV infection, although temporary withdrawal augmented viral load (Donahoe et al., 1993), but in another, their progression was more rapid (Chuang et al., 1997). Neither acute nor chronic morphine or withdrawal altered FIV infection in cats, but the number of animals was small and the variance in FIV load large (Barr et al., 2003).

Cocaine has also been investigated in regard to effects on HIV infection and found to potentiate replication in vitro systems (Peterson et al., 1992; Bagasra and Pomerantz, 1993). Cocaine has also been shown to up-regulate DC-SIGN, a molecule on the surface of human dendritic cells that can act as a receptor for HIV (Nair et al., 2005). In addition, a provocative paper reported that mice with severe combined immunodeficiency, that were reconstituted with human leukocytes and infected with HIV, had enhanced replication of the virus after cocaine treatment (Roth et al., 2002). The fact that opioids and cocaine can alter replication of HIV in cell culture in vitro certainly suggests that the drugs should be able to alter HIV progression in vivo. Isolation of variables in the laboratory permits elimination of confounding factors in epidemiologic studies in humans, such as poly-drug abuse, and also standardizes drug dosage. Thus, there is considerable evidence from laboratory studies supporting a role for drugs of abuse in potentiating HIV infection.

Summary

In general, opioids and cannabinoids have been found to be suppressive in a wide variety of assays of immune responsiveness. The literature on cocaine is smaller and less consistent. An extension of these observations is the assessment of effects of the drugs on resistance to infection, a consequence of alterations in immune function. Both opioids and cannabinoids have been shown to sensitize animals to a variety of experiment infections. Interest in the effects of the opioids on HIV progression is sparked by the epidemiological intersection of intravenous drug abuse and incidence of HIV. In vitro studies give robust results showing augmentation of HIV replication in the presence of opioids. A single study with cocaine, using an immunodeficient mouse repopulated with human lymphoid cells, shows enhanced replication of HIV in the presence of the drug. Together, the literature suggests substantial effects of drugs of abuse on immune competence in general, resulting in immunosuppression. The implications of the research are that drug abuse increases vulnerability to infection. These studies also reinforce the existence of physiological pathways between the neural and immune systems mediated by opioids and cannabinoids.

Acknowledgments. We thank Dr. Martin Adler, Director of the Center for Substance Abuse Research, Temple University School of Medicine, for critical reading of the manuscript. This work was supported by NIDA grants DA06650, DA11130, DA11134, DA13429, DA14223 and DA14230.

Review Questions/Problems

1. It is observed that morphine given subcutaneously suppresses responses of spleen cells put into tissue culture with the T-cell mitogen Concanavalin A (Con A).

- Mice with a disruption of the gene coding the mu opioid receptor (Mu Opioid Receptor knock-out mice), would not show suppression to Con A.
- Morphine acts mainly through the kappa opioid receptor.
- Morphine is mainly metabolized to heroin when it is injected in vivo.
- Methyl-morphine could not be used to determine if peripheral receptors or brain receptors are involved in the immunosuppression.
- None of the above.

2. In regard to cannabinoids:

- They are proteins.
- They exert their effects primarily by interdigitating into cell membranes.
- There is evidence that they polarize the immune response towards a Th1 type phenotype.
- There is evidence that they polarize the immune response towards a Th2 type phenotype.
- They have no direct effects on cells of the immune system.

3. In regard to the immune system, morphine has been shown to:

- Elevate antibody responses to various antigens.
- Elevate responses to the B-cell mitogen, lipopolysaccharide (LPS).
- Elevate delayed-type hypersensitivity (DTH) responses.
- Increase phagocytosis by macrophages.
- Depress natural killer (NK) cell activity.

4. Cocaine:

- Has no effect on the immune system.
- Exacerbates HIV replication in a mouse/human model of viral replication.
- Binds to the delta opioid receptor.
- Depresses IL-2 production.
- All of the above.

5. In regard to infections and drugs of abuse:

- Morphine sensitizes mice to infection with *Legionella pneumophila* (Legionnaires' Disease).
- Δ^9 -THC sensitizes mice to *Salmonella* infection.

- c. Morphine and Δ^9 -THC have direct effects on the ability of bacteria to grow in broth cultures.
 - d. Morphine can affect resistance to infection by altering the activity of phagocytes.
 - e. Intravenous drug abusers have a rate of infection the same as the general population.
- 6. Morphine most probably affects the progression of HIV infection by all of the following EXCEPT:**
- a. Changing the level of chemokine receptors.
 - b. Changing the level of chemokines.
 - c. Causing T-cells to undergo uncontrolled cell division.
 - d. Mediating heterologous desensitization of chemokine receptors.
 - e. Altering cytokine levels.
- 7. Which of the following statements is true:**
- a. Opioids, cannabinoids, and cocaine uniformly suppress the activity of NK cells.
 - b. The use of N-methylmorphine substantiated the direct effects of opioid-induced NK cell suppression.
 - c. Mice lacking the μ -opioid receptor do not have suppressed NK cell activity in response to morphine treatment.
 - d. Δ^9 -THC prevents NK cell proliferation by inhibiting the secretion of TGF- β .
 - e. Morphine inhibits NK cell activity by inducing endogenous cannabinoid levels.
- 8. Opioids modulate phagocyte activity by:**
- a. Increasing phagocytic uptake of bacteria.
 - b. Decreasing apoptosis of phagocytic cells.
 - c. Enhancing maturation of bone marrow cells into macrophages.
 - d. Decreasing their ability to make microbicidal compounds in vitro.
 - e. Decreasing maturation of lymphocytes in the bone marrow.
- 9. Immune cells treated with morphine:**
- a. Uniformly have markers of activation.
 - b. Display altered levels of pro-inflammatory chemokines, but chemokine receptor numbers remained unchanged.
 - c. Display bi-directional heterologous desensitization between opioid receptors and certain chemokine receptors.
 - d. Clearly have inhibition of Th2 cytokine responses.
 - e. None of the above
- 10. Which of the following statements is true:**
- a. Δ^9 -THC induces its effects through both CXCR4 and CCR5.
 - b. Both Δ^9 -THC and morphine have been shown to induce the expression of pro-inflammatory chemokines, such as MCP-1 and IL-8.
 - c. Like cannabinoids and morphine, cocaine treatment increases TNF- α and IL-1.
 - d. Cocaine uniformly suppresses cytokine and chemokine production when given in vivo or applied to cells of the immune system in vitro.
 - e. Opioids have no effect on antibody formation.
- 11. Morphine and/or DAMGO treatment results in decreases in which of the following?**
- a. Apoptosis
 - b. Pro-inflammatory chemokine production
 - c. Serum antibody responses
 - d. TGF- β
 - e. All of the above
- 12. Inhibition of T cell responses is observed for which of the following drugs of abuse?**
- a. Morphine
 - b. Δ^9 -THC
 - c. Cocaine
 - d. All of the above
 - e. None of the above
- 13. The initial evidence suggesting that opioid receptors are expressed by cells of the immune system was:**
- a. Results showing impairment of T cells to rosette to sheep red blood cells in the presence of morphine.
 - b. Studies examining functions of the CB1 and CB2 receptors.
 - c. Primate studies examining disease incidence in self-administration of heroin
 - d. Biochemical analyses of lymph nodes in heroin addicts.
 - e. Studies showing increased HIV infection in heroin abusers.
- 14. All of the following statements are true EXCEPT?**
- a. In vitro studies have shown Δ^9 -THC biases the immune response towards a Th2 cytokine profile.
 - b. Cocaine administration stimulated production of the anti-inflammatory cytokine IL-10, while simultaneously suppressing IFN γ .
 - c. Activated human PMNs show enhanced functional activity in response to cocaine.
 - d. The effects of opioids, cannabinoids, and cocaine on immune system function are compounded by the involvement of the HPA axis.
 - e. Chemokine expression is induced by morphine administration.
- 15. Evaluation of the effects of drugs of abuse can be complicated by a number of factors, including:**
- a. The effects of the sympathetic nervous system on immune cell function.
 - b. The effects of the HPA axis on immune cell function.

- c. The capacity of cells of the immune system to produce endogenous opioids.
 - d. The production of endogenous cannabinoids in the periphery.
 - e. All of the above.
- 16. The function of G protein-coupled receptors, such as the opioid and cannabinoid receptors, can be regulated by the process of heterologous desensitization. Which of the following statements is true about this regulatory mechanism?**
- a. This process occurs when the activation of one receptor leads to an increased expression of a second receptor.
 - b. This process only occurs between receptors expressed on the surfaces of adjacent cells.
 - c. This process cannot occur between receptors expressed on the same cell.
 - d. This is a process that appears to involve transphosphorylation of G protein-coupled receptors.
 - e. All of the above
- 17. Both opioids and cannabinoids have been shown to sensitize animals to a variety of experimental infections. The impact of drugs of abuse on resistance to infectious agents can be difficult to evaluate because:**
- a. Drug abuse rarely involves the administration of a single drug, and the effects of poly-drug abuse are poorly understood.
 - b. Drug abusers are exposed more frequently to pathogenic agents than non-abusers.
 - c. A number of additional factors, which are hard to control, impact on measurement of the immune competence of drug abusers, including the dose of the drug and the time since it was last taken.
 - d. The contributions of legal drug use, including nicotine and alcohol, can complicate the effects of illegal drug abuse.
 - e. All of the above.
- 18. All of the following influence the effect of opioids on susceptibility to HIV infection EXCEPT:**
- a. Opioids alter the expression of chemokine receptors that are co-receptors for HIV-1.
 - b. Opioids increase the expression of some chemokines, which may promote the attraction of additional susceptible target cells for HIV infection.
 - c. Opioids increase the expression of chemokines, which, for an individual cell, may block viral replication by blockading the chemokine coreceptor.
 - d. Opioids alter the phagocytic activity of neutrophils, and this would be expected to significantly alter the kinetics of the infection.
 - e. Opioids would be expected to alter the expression of cytokines that may, in turn, alter the replication rate of the virus in monocytes and T cells.

38.1. Introduction

The immune system is subject to modulation by a number of environmental cues including, but not limited to, microbial infections, toxic agents, stress, drugs and trauma. Endogenous immunoregulatory factors include those produced by the nervous and endocrine systems. This chapter discusses how these factors, as well as drugs targeting the immune, autonomic and central nervous systems, affect the immune system.

38.2. The Autonomic Nervous System

This section provides a review of the anatomy and physiology of the autonomic nervous system (ANS) accompanied by a brief description of some of the important drugs which modify its actions. A summary of the interaction between the immune system and the ANS is also included. An extensive discussion of the anatomy and physiology of the ANS can be found in the *Primer on the Autonomic Nervous System* (Robertson, 2004). Detailed information on the pharmacology of the ANS can be found in *Goodman & Gilman's The Pharmacological Basis of Therapeutics* (Brunton et al., 2006).

38.2.1. Anatomy and Physiology

The ANS, a major subdivision of the peripheral nervous system, functions as a regulator of tissues throughout the body. The control of these tissues is the responsibility one or both of the two divisions of the ANS, the parasympathetic nervous system and the sympathetic nervous system including the

adrenal medulla, which act either individually or in opposing or complimentary modes. The ANS regulates a variety of activities essential to life including cardiac output, blood flow to various organs, digestion, elimination and various other functions. The other major subdivision of the peripheral nervous system, the somatic nervous system (SNS), controls functions such as locomotion, respiration and posture.

The ANS differs from the SNS in that: (a) the CNS is connected with effector cells on autonomic end organs via two nerve fibers, (b) the synapses (ganglia) linking the CNS with these tissues are located outside the CNS, (c) the ANS uses both norepinephrine (NE) and acetylcholine (ACh) as neurotransmitters rather than only ACh, and (d) the ANS is concerned with the homeostasis of the internal environment of the body rather than locomotion, respiration and posture. The autonomic nerve fibers connecting the CNS to peripheral tissues originate in the spinal and cranial regions (preganglionic) and synapse with the cell bodies of the motor neurons in the autonomic ganglia (postganglionic). This arrangement serves to relay CNS impulses to peripheral effector cells and also to serve as a control loop for autonomic reflex actions. Visceral afferent fibers also provide input to the autonomic nervous system. CNS impulses are influenced by various areas of the brain and integrated primarily by the action of the hypothalamus and the solitary tract nucleus.

The ANS is organized into two divisions, the parasympathetic or craniosacral portion and the sympathetic or thoracolumbar portion. The ratio of pre- to postganglionic fibers is generally 1:1 in the parasympathetic division and not all tissues receive innervation (e.g., spleen, axilla sweat glands, and most blood vessels). In contrast, the ratio of pre- to postganglionic fibers is 1:20 in the sympathetic division with unlimited distribution. This arrangement underscores the more discreet action of the parasympathetic division as compared to the initiation of action in several tissues upon activation of the sympathetic division, the so-called "flight or fight" response. Parasympathetic action is conservative relative to the well-being of the individual whereas sympathetic action is responsive (Table 38.1).

TABLE 38.1. Simplified table of ANS activity on some organ systems.

Organ/System	Sympathetic division		Parasympathetic division	
	Action	Receptor ^a	Action	Receptor
BRONCHIOLAR SMOOTH MUSCLE	Relaxes	β_2	Contracts	M
EYE				
Iris	Contracts	α_1	Contracts	M
Radial muscle			Contracts	M
Sphincter muscle				
Ciliary muscle				
GASTROINTESTINAL TRACT				
Smooth muscle	Relaxes	β_2	Contracts	M
Sphincters	Contract	α_1	Relaxes	M
Secretion			Increases	M
GENITOURINARY SMOOTH MUSCLE				
Bladder wall (detrusor)	Relaxes	β_2	Contracts	M
Sphincter & trigone	Contract	α_1	Relax	M
Uterus, pregnant	Relaxes	β_2	Erection	M
Penis, seminal vesicles	Contracts	α_1		
	Ejaculation	α_1		
HEART				
Sinoatrial node	Accelerates	β_1	Decelerates	M
Contractility	Increases	β_1	Decreases (atria)	M

Skeletal muscle vessels	Relax or	β_2		
	Contract	α_1		

^a α —Alpha adrenergic receptor; β —Beta adrenergic receptor; M—Muscarinic receptor.

Neuronal impulses between the CNS and either division of the ANS require both axonal conduction and synaptic or junctional transmission. Synaptic transmission (nerve to nerve) and junctional (nerve to effector organ) transmission are dependent upon the release of neurotransmitter from presynaptic neurons. The majority of clinically significant drugs that alter neuronal activity act at the level of synaptic or junctional transmission. This process is primarily dependent upon the influx of Ca^{+2} through voltage-gated channels to a threshold level that initiates the process of exocytosis. This multi-step process releases significant amounts of neurotransmitter into the synaptic cleft sufficient to open postsynaptic ion channels or activate G protein coupled receptors. The result may be either stimulation or inhibition of the end organ (cardiac muscle, smooth muscle, exocrine glands).

ACh is the transmitter released by: (a) all preganglionic fibers including those innervating the adrenal medulla; (b) postganglionic parasympathetic fibers to smooth muscle, heart and exocrine glands; and (c) postganglionic sympathetic fibers to sweat glands. In contrast, NE is the transmitter released by: (a) postganglionic sympathetic fibers to smooth muscle, heart and glands; and (b) adrenal medulla. The effects of either neurotransmitter are mediated by specific receptors.

ACh acts on cholinergic receptors (classified muscarinic or nicotinic) whereas NE acts on adrenergic receptors (classified α or β). Subtypes of muscarinic (M_{1-3}), nicotinic ($N_{N \text{ or } M}$), (α_{1-2}) and (β_{1-3}) receptors exist as well.

38.2.2. Neurotransmission

ACh is synthesized from choline and acetylCoA by the action of choline acetyltransferase in the cytosol of nerve terminals and packaged in synaptic vesicles for release into the synaptic cleft in response to neuronal depolarization. Either muscarinic or nicotinic receptors are responsible for the effects of ACh (e.g., increase in muscle tone or glandular secretion), which are subsequently terminated by the action of acetylcholinesterase (AChE). Choline, as a product of this reaction, can be actively transported into the nerve ending for conversion to ACh once again. ACh synthesis is responsive to the prevailing level of intracellular choline. Muscarinic receptor responses include increases in intracellular Ca^{+2} and activation or inhibition of various protein kinases mediated by G protein coupled receptors. Nicotinic receptor activation results in the opening of ligand gated ion channels and the influx of Na^{+} and the generation of postsynaptic (ganglia) or endplate (skeletal muscle) potentials.

NE is synthesized by tyrosine hydroxylation (*meta* ring position) followed by decarboxylation and side chain β carbon hydroxylation. The synthesis of this catecholamine is regulated by tyrosine hydroxylase. Tyrosine hydroxylation is also a key step in the synthesis of two other important catecholamines, dopamine and epinephrine. NE is packaged via active transport into synaptic (or chromaffin) vesicles prior to release by neuronal depolarization. The effects of NE are mediated by adrenergic receptors (α or β) which are G protein coupled resulting in either increases or decreases in smooth muscle tone as well as increases in cardiac rate and contractility. These effects arise out of receptor mediated increases in intracellular Ca^{++} and activation or inhibition of various protein kinases. The effects of NE are terminated essentially as a result of its active transport into the presynaptic nerve ending via an energy and Na^+ dependent process which utilizes the norepinephrine transporter (NET). Ultimately, NE and other catecholamines are metabolized by monoamine oxidase (MAO) and catechol-O-methyltransferase (COMT).

The effects of both ACh and NE can be enhanced by the co-localization of agents such as the neuropeptides vasoactive intestinal peptide (VIP) and neuropeptide Y (NPY). For example, VIP can increase ACh induced salivary secretion (Lundberg and Hokfelt, 1983) and NPY can enhance the vasoconstrictive effects of NE (Wahlestedt et al., 1985). In theory, agents mimicking or blocking the effects of these neuropeptides should expand the opportunities for control of various disease conditions such as Sjögren's disease and hypertension. However, significant advances in such therapy are yet to be realized.

38.2.3. Pharmacology of Autonomic Agents

Neurotransmission at both cholinergic and adrenergic synapses can be influenced by a variety of naturally occurring and synthetic drugs (Table 38.2). For example, ACh secretion is drastically reduced in the presence of botulinum toxin which contains proteases that cleave proteins vital to the process of exocytosis. Nicotine, one of the active ingredients in tobacco can mimic the effects of ACh and increase (or decrease at high doses) autonomic ganglionic transmission as well as that at the

skeletal motor endplate. The effects of nicotine on autonomic ganglia can be prevented by prior treatment with agents such as trimethaphan. The widespread effects of this agent due to its effects on all autonomic ganglia have relegated it to use primarily as an experimental agent. Conversely, d-tubocurarine, an active ingredient present in South American arrow poison, is an effective muscle relaxant due its ability to block nicotinic receptors on skeletal muscle and finds use as a preoperative medication. Muscarine, a constituent of certain mushroom species, can mimic the stimulatory effect of ACh on various smooth muscles and exocrine glands. The belladonna alkaloids, which are found in a variety of plants, can antagonize the effects of ACh on muscarinic receptors.

NE secretion can be effectively decreased by administration of reserpine, an alkaloid isolated from a small woody perennial found in India (Rauwolfia), which has a high affinity for the vesicular monoamine transporter-2 (VMAT-2) and as such prevents NE storage. Alternatively, NE secretion can be increased by administration of tyramine (decarboxylated tyrosine), which is a constituent of a variety of foods including red wine, pickled herring and cheese. Amphetamine has a similar effect, which is most prominently manifested in the CNS. The termination of NE effects can be circumvented by the administration of cocaine, which blocks NE transport into presynaptic nerve endings (NET) an effect, which is also shared by some of the first generation antidepressants, such as imipramine.

The structures of both ACh and NE or alkaloids possessing some of the properties of these agents have been modified to produce a variety of agents that mimic or block the effects of these neurotransmitters. Bethanechol is an ACh derivative with a longer duration of action and selectivity for muscarinic receptors. This agent increases smooth muscle tone and is useful in the treatment of urinary retention and gastroesophageal reflux disease. The structure of the classic AChE inhibitor, physostigmine (eserine, an alkaloid) has been modified (neostigmine) to limit absorption and increase nicotinic receptor stimulation resulting in its use in amelioration of the symptoms of the autoimmune disease, myasthenia gravis. Further modification of the basic structure has yielded agents, e.g., rivastigmine, of some benefit in improving cognition in Alzheimer's disease. AChE is the target for many of the organophosphorus insecticides as well as extremely toxic nerve gases such as soman. Prompt and aggressive treatment with cholinesterase reactivators such as pralidoxime (pyridine-2-aldoxime methyl chloride) reverses the toxic effect of the organophosphorus compounds within moments and restores the response to skeletal motor nerve stimulation.

Perhaps the most widely known agent to alter cholinergic transmission is the belladonna alkaloid, atropine. This agent is relatively selective for muscarinic receptors and as such decreases exocrine gland secretion, smooth muscle tone and the effects of vagal nerve stimulation of the heart. Atropine has several clinical applications including use as a preoperative medication, post-myocardial infarction to increase heart

TABLE 38.2. ANS drugs and their receptors.

Cholinergic		Adrenergic	
		Alpha (α) adrenergic	Beta (β) adrenergic
Muscarinic	Nicotinic		
Acetylcholine	Acetylcholine	Amphetamine	Amphetamine
Atropine	Botulinum toxin	Cocaine	Cocaine
Bethanechol	Neostigmine	Epinephrine	Dobutamine
Botulinum toxin	Nicotine	Norepinephrine	Epinephrine
Ipratropium	Physostigmine	Phenylephrine	Isoproterenol
Muscarine	Rivastigmine	Prazosin	Metoprolol
Physostigmine	Soman	Reserpine	Norepinephrine
Rivastigmine	Trimethaphan	Tyramine	Propranolol
Soman	D-Tubocurarine		Terbutaline
Tropicamide			Tyramine

rate and in the treatment of organophosphorus toxicity. Structural modification of this compound has produced shorter acting agents, e.g., tropicamide in eye examinations and agents with limited ability to cross cell membranes, e.g., ipratropium as an airway smooth muscle relaxant. The wide availability of belladonna alkaloid containing plants such as jimson weed in the U.S. has resulted in the misuse of these agents for recreational purposes due to their ability to produce CNS stimulation. As mentioned above, nicotinic receptor antagonists have limited clinical applications.

The naturally occurring catecholamine, epinephrine, has a variety of effects at adrenergic receptors including both smooth muscle stimulation and relaxation, increased cardiac activity and catabolic effects on triglycerides and glycogen. Epinephrine finds use in cardiac stimulation after cardiac arrest, relief of bronchoconstriction, lowering of intraocular pressure in open angle glaucoma and elevation of blood pressure. Modification of the ethylamine side chain of the catecholamine structure results in agents with selective actions on β adrenergic receptors, e.g., isoproterenol, as a smooth muscle relaxant and cardiac stimulant and dobutamine, as a cardiac stimulant. Elimination of one or both of the catechol hydroxyl groups produces compounds with a longer duration of action including additional receptor selectivity dictated by modifications to the ethylamine side chain. For example, phenylephrine is a non-catechol compound containing a hydroxyl group on the side chain β carbon with preference for α receptors. This agent is an effective blood pressure elevating agent that is also used to dilate the pupil prior to an eye examination. Terbutaline is also a non-catechol compound that contains a bulky substituent on the side chain amine resulting in selective action on the β_2 receptor subtype. This agent is similar to isoproterenol and is therefore an effective airway relaxing agent but with reduced cardiac stimulant properties.

Antagonists for α adrenergic receptors are directed primarily toward the α_1 subtype and are therefore useful blood pressure lowering agents, e.g., prazosin. In contrast, agents that block β adrenergic receptor mediated responses are best represented by propranolol, which can block both the β_1 and β_2 adrenergic receptor subtypes. Propranolol is widely used as a cardiac depressant and blood pressure lowering agent. Structural modifications of propranolol produce agents with a longer duration of action and selectivity for β_1 adrenergic receptors. Agents such as metoprolol have a reduced ability to increase airway resistance while still being able to lower blood pressure and depress cardiac activity.

38.2.4. Autonomic Regulation of Immunity

Infection, injury and trauma initiate a series of immune reactions to overcome the effects of various pro-inflammatory mediators resulting in repair of injured tissues and wound healing. The arbiter of this response is the brain, which communicates with the immune system via neurotransmitters, cytokines and hormones (Figure 38.1). Activation of

the immune system by the brain occurs through two major pathways: (a) the hormonal response pathway which results in the activation of the hypothalamic-pituitary-adrenal axis releasing glucocorticoids; and (b) the ANS which releases ACh and NE from the parasympathetic and sympathetic divisions, respectively, to modulate the activity of lymphoid tissues. In addition these tissues contain receptors for a variety of neuropeptides (Steinman, 2004) which are co-released with either ACh or NE and are likely to exert prominent effects on the immune system. Classically the sympathetic portion has been viewed as the primary division of the ANS, which influences the immune system arising from the seminal work of Hans Selye (Selye, 1936). However, recent data also demonstrates interplay between the parasympathetic division and the immune system (Czura and Tracey, 2005).

The sympathetic nervous system innervates the major lymphoid organs such as the spleen with nerve fibers reaching both the vasculature and the parenchyma where lymphocytes, primarily T cells (T helper type 1–2, T_H1 , T_H2), reside (Friedman and Irwin, 1997). T cells possess receptors for both norepinephrine and neuropeptide Y that are released in response to sympathetic nerve stimulation. The adrenergic receptors are primarily the β_2 subtype, which is consistent with data demonstrating that β_2 agonists can markedly influence the immune system (Kohm and Sanders, 2001). For example, stimulation of T cell receptors results in increased cyclic AMP formation, which can modulate cytokine expression, i.e., decreasing

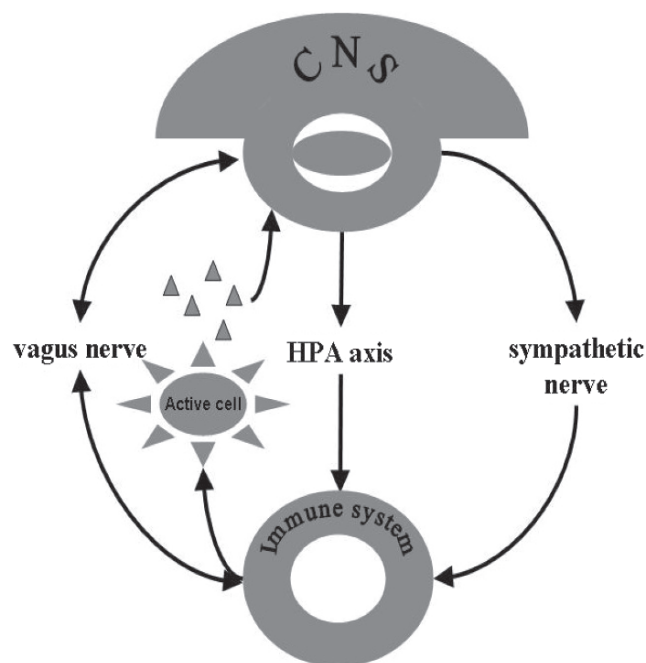

FIGURE 38.1. Interaction between the CNS and the immune system via the ANS. Signals from the CNS influence the immune system through activation of either the parasympathetic (vagus) or sympathetic portions of the ANS. (HPA - hypothalamic-pituitary-adrenal; Δ - cytokine)

TNF- α and increasing IL-8 (Webster et al., 2002). Consistent with this, selective β_2 receptor antagonists such as butoxamine can antagonize the corticotrophin-releasing factor-induced reduction in natural killer (NK) cell activity (Irwin et al., 1990). Sympathetic nerve stimulation also enhances T_H2 cytokine production while inhibiting T_H1 cytokine production. Thus, β_2 receptor agonists can suppress interferon- γ (IFN- γ) production by T_H1 cells, an effect, which can be blocked by propranolol. Interestingly, prion presence in the brain has been linked to an interaction between splenic monocytic cells and the sympathetic nervous system (Steinman, 2004).

In addition to the effects mediated by the sympathetic nervous system, afferent activation of the vagus nerve (parasympathetic nervous system) through the detection of inflammatory stimuli, transmits signals to the brain activating a reflex response (Czura and Tracey, 2005). The vagus nerve is also the efferent arm of this reflex, which results in the release of ACh and binding with macrophage nicotinic receptors. Activation of the $\alpha7$ nicotinic receptor on macrophages leads to cellular deactivation and inhibition of cytokine release. This effect can be blocked by the prior administration of mecamylamine, a nicotinic receptor antagonist with selectivity for neuronal receptors (Saeed et al., 2005). Thus development of agents selective for either adrenergic β_2 receptors or $\alpha7$ nicotinic receptors provides a promising avenue for the treatment of inflammatory diseases.

38.3. CNS Pharmacology

It is well established that the immune system is regulated by the CNS via the HPA axis and the sympathetic nervous system. Regulation of the hypothalamus by other CNS regions is complex but the end result is that stimulation leads to increased release of CRF from the hypothalamus. CRF, in turn, acts on the anterior pituitary to cause release of ACTH into the circulation. ACTH produces release of glucocorticoids from the adrenal medulla. The glucocorticoids, such as cortisol, have powerful regulatory effects on immune system function, suppressing the production and release of pro-inflammatory cytokines and inhibiting other inflammatory processes. This is covered in greater detail in Chapter 34.

More recently it has become apparent that this relationship is reciprocal in nature, i.e., the immune system also can regulate the HPA axis and have significant effects on the CNS (see Carlson, 2003; Eskandari et al., 2003, for reviews). Chemokines, cytokines and other mediators released by the immune system can alter CNS function and abnormally high levels of some cytokines, such as IL-6, are associated with mental disorders, such as depression (see Chapter 34). In addition it is now clear that some neurohormones once thought to be exclusively neuronal are also produced by immune cells and that some immune system mediators are expressed by cells within the CNS. A consequence of this is that drugs whose primary site of action has classically been defined as the cen-

tral nervous system may play important roles in modulating immune system function as well. This section provides a discussion of the pharmacology of three such classes of drugs. These are the opioid drugs, sedative-hypnotic agents and general anesthetics. The mechanism of action of these drugs will be described insofar as it is known, the traditional clinical uses of these drugs described briefly, and their potential involvement with the immune system will be reviewed.

38.3.1. Central Nervous System

The CNS is one of the most complex organ systems in the body. There are multiple ways in which the CNS can be organized: by anatomic regions based on groupings of cell bodies and neuronal pathways, by neurotransmitter and neurohormonal systems, by cell types (neurons, astrocytes, microglia, blood vessels, etc.), by physiological function and by areas involved in particular disease states. While these organizational systems parallel one another to some extent, there is also considerable intermingling and overlap of one system with another when considering a specific issue. This is made even more complex by the ability of the CNS to compensate for and to use alternate systems in the face of brain areas injured by disease or physical damage. A detailed understanding of these various organizational systems is beyond the scope of this book and can best be obtained from texts dedicated to each.

38.3.2. Opioid Drugs and Opioid Receptors

The opioid drugs are the most commonly used drugs to treat moderate to severe pain throughout the world. Opium, the original substance derived from the opium poppy, *Papaver somniferum*, has been used for millennia as an analgesic agent. The prototype opioid drug, morphine, which is derived from opium, has been used for almost two hundred years and is still the most effective opioid analgesic available. The opioid drugs and their endogenous counterparts, the endorphins, dynorphins and enkephalins, are agonists at opioid receptors. The opioid receptors play a role in numerous physiological and pathological functions. These receptors are important for nociception, emotional behavior (as part of the limbic system) and the reinforcement of behavior (reward system). They are important in regulation of respiration, GI function and immune function. These receptors also play an integral role in dependence upon opioid drugs and appear to play a significant role in dependence produced by other chemically unrelated drugs.

38.3.2.1. Opioid Receptors

There are four major classes of opioid receptors: μ , κ , δ , and NOP receptors (see <http://www.iuphar-db.org/GPCR/ChapterMenuForward?chapterID=1295>). Pharmacological studies in many species and knockout studies in mice indicate that the μ opioid receptors (MOP receptors; MOR; OP_3 receptors) are involved in most of the clinically important effects associated with opioid drugs (Matthes et al., 1996;

Sora et al., 1997). Mu opioid agonists, such as morphine and codeine, are used clinically to treat moderate to severe pain, to control cough and diarrhea, and in the treatment of drug dependence (Gutstein and Akil, 2006). Kappa opioid receptors (KOP receptors; KOR; OP_2 receptors) are also involved in regulation of nociception. Agonists at KOP receptors, such as pentazocine and butorphanol, are used as analgesic agents. High levels of kappa agonists are frequently associated with dysphoria, in contrast to the euphoria that can be produced by agonists acting primarily on MOP receptors. Delta opioid receptors (DOP receptors; DOR; OP_1 receptors) appear to be involved in pain perception, based on their anatomic localization, and may also be involved in drug dependence. There are currently no drugs specifically targeted to DOP receptors in clinical use. While early delta specific agonists were frequently associated with the production of seizures, there is an emerging set of data that suggests seizure liability is not a fundamental characteristic of delta agonists and that agonists at DOP receptors may be useful in treating pain while avoiding the degree of dependence associated with MOP receptor agonists.

The last currently recognized member of the opioid receptor family is the NOP receptor (nociceptin/orphanin FQ receptor; N/OFQ receptor; ORL1 receptor; OP_4 receptor). Most opioid agonists have a much lower affinity for NOP receptors compared to the other opioid receptors. Conversely, the endogenous ligand for the NOP receptors, nociceptin or orphanin FQ (OFQ/N), is structurally similar to dynorphin but has a high affinity only for the NOP receptor (Mogil and Pasternak, 2001). Our understanding of the function of the NOP receptor and its pharmacology is limited and the therapeutic involvement of these receptors, including their relationship with the immune system, is not known.

Within the CNS, opioid receptors are widely distributed and are co-expressed in many of the same regions (Mansour and Watson, 1993; Neal et al., 1999). MOP receptors are found throughout the CNS with dense receptor expression in the basal ganglia, limbic structures, some thalamic nuclei and in the dorsal horn of the spinal cord. They are also found in regions involved in nociception and sensorimotor regulation, including the periaqueductal grey and several thalamic nuclei. KOP receptors have a similar widespread distribution with dense receptor expression in the basal ganglia and limbic structures, some thalamic nuclei and the dorsal horn of the spinal cord. Kappa receptors display striking differences between species, playing a much more prominent role in primates, including humans, than in rodents. Delta receptors are more restricted in distribution but are also found densely expressed in basal ganglia and limbic structures. Finally, NOP receptors are found throughout the CNS, with highest levels in the cortex, hypothalamus, hippocampus, some amygdaloid nuclei, as well as spinal cord (Neal et al., 1999; Florin et al., 2000; Bridge et al., 2003). NOP localization suggests a role in multiple functions, including nociception, the reward system, and stress response. The similar distribution of opioid receptors in many brain regions offers the possibility that they

may function as both homomeric and heteromeric receptors (Gomes et al., 2000). A number of studies have shown that heterodimerization of opioid receptors leads to distinct pharmacological characteristics (Gomes et al., 2004; Devi, 2001). It should be noted that there are considerable species differences in the distribution of some opioid receptors (Mansour et al., 1988; Bridge et al., 2003).

38.3.2.2. *Endogenous Opioid Neuropeptides*

The endogenous ligands for the opioid receptors are peptides known as the endorphins (endogenous morphine) or opiopeptides. These include the pentapeptides methionine-enkephalin and leucine-enkephalin and a heptapeptide and octapeptide version of methionine-enkephalin, all derived from preproenkephalin; β -endorphin derived from proopiomelanocortin; α - and β -dynorphin derived from prodynorphin; endomorphin-1 and -2, whose precursor has not been definitively identified; and orphanin FQ or nociceptin, derived from OFQ/N precursor protein. These peptides are discussed in more detail in Chapter 34.

38.3.2.3. *Opioid Drug Effects on the Immune System*

The first data indicating that opioid drugs affect immune function came from the work of Wybran, who demonstrated that morphine could modify T cell function (Wybran et al., 1979). Binding of opioid ligands to immune cells has been demonstrated by many laboratories, as described in detail below. The binding sites for opioid drugs include both classical opioid sites, for which binding is blocked by naloxone or another opioid antagonist, and "non-classical" opioid receptors, which are not inhibited by classical antagonists and usually have a low affinity for standard opioid agonists. While the "non-classical" binding sites share many of the properties of G protein coupled receptors (GPCR), such as saturability and sensitivity to cations and GTP γ S, their anomalous pharmacology leaves the picture clouded. If these are indeed opioid receptors at which either endogenous or exogenous opioids could be expected to exert an effect, this has yet to be established. Given that the NOP receptor has a distinct pharmacology and low affinity for morphine, and that the NOP receptor appears to be a physiologically important receptor, it is possible that these "non-classical" opioid receptors will prove important in immune function. Similarly, the discovery of splice variants for the MOP receptor that have differing pharmacologies but whose function is currently unknown (Pasternak, 2001; Cadet, 2004) indicates how much is yet to be learned about opioid receptors.

38.3.2.3.1. *Opioids and the Immune System (In Vitro Studies)*

Studies of opioid effects on immune cell function have relied heavily on the use of specific cell lines in culture. This is due to the expression of opioid receptors on subpopulations of cells,

making it difficult to detect receptors or receptor function in a mixed cell population. There have been extensive reviews of the many features of opioid effects on immune cells (Bidlack et al., 2006; McCarthy et al., 2001).

Delta and kappa opioid receptors have been demonstrated on several immune cells including lymphocytes, peripheral blood polymorphonuclear leukocytes and macrophages (Sharp, 2006). Parallel to this, mRNA for MOP, DOP and KOP receptors also have been found in many immune cell types, including T and B cells, lymphocytes, macrophages and peripheral blood mononuclear cells. Both morphine and kappa-selective agonists increase KOP receptor expression in a human lymphocytic cell line (Suzuki et al., 2001). Activation of T cells by anti-CD3- ϵ leads to increased expression of DOP receptors, priming these cells for greater response to opioids, either endogenous or exogenous (Shahabi et al., 2006; Sharp et al., 2005). Treatment of peripheral blood mononuclear cells with morphine dose-dependently promotes T_H2 cell differentiation, apparently by increasing IL-4 production. This response was lost in cells from MOP receptor knockout mice. These studies point to a suppression of the immune system by morphine. The resulting failure of cell-mediated immunity plays a significant role, in turn, in increased morbidity and mortality following trauma or major surgery (Roy et al., 2001, 2006).

Opioids can regulate intracellular signaling in immune cells. As would be expected, regulation of intracellular signaling depends on the receptor subtype and the cell line being studied. DOP receptors inhibit adenyl cyclase in human T cells in a pertussis toxin-sensitive manner, indicative of a GPCR linked to Gi/o (Sharp et al., 1996). KOP receptors act in a similar manner in the R1.1 thymoma cell line (Lawrence and Bidlack, 1993). Many other studies have been carried out in the same vein but the results are not always consistent, similar to other studies trying to decipher regulation of immune system function (Sharp, 2006). This supports the idea that regulation of the immune system by opioids, both endogenous and exogenous, is complex and the direction of this regulation is dependent upon many variables. It also suggests that many of the findings reported to date will prove to be highly specific to the experimental paradigm and may not translate well into the *in vivo* situation.

Given the expression of opioid receptors and endogenous opioid peptides by cells in the immune system, the question naturally arises as to whether the opioid drugs have an impact on immune system function. While many studies have addressed this question, there is much to be learned (Bidlack et al., 2006; McCarthy et al., 2001). It appears that KOP receptors play a role in T-cell development since they are highly expressed on immature thymocytes and diminish in expression as these cells mature. KOP receptor-selective agonists inhibit synthesis of IL-1 and TNF- α but not IL-6 in a macrophage cell line (Belkowski et al., 1995). DOP receptors can stimulate T-cell chemotaxis based on the use of highly specific DOP receptor agonists (Heagy et al., 1990).

It has also been shown that morphine, primarily through MOP receptors, can alter viral replication in immune cells. Morphine inhibits the anti-HIV activity of CD8⁺ T cells *in vitro*, possibly through inhibition of IFN- γ production and activity. This leads to increased HIV production (Wang et al., 2005b). In a similar manner, morphine and, even more so, morphine withdrawal increase Hepatitis C virus replication in human hepatoma cell lines by suppressing interferon- α expression (Wang et al., 2005a). These studies suggest that opioid abuse by people with these and other viral infections can contribute to maintaining and promoting the viral infection. This points to the importance of gaining a thorough understanding of the effects of opioids on the immune system, especially in cases of chronic infection.

38.3.2.3.2. Opioids and the Immune System (*in vivo* studies)

Are the multiple effects of opioids and opioid receptor stimulation on the cell biology of immune cells reflected clinically? The answer is not clear at present. It is well known that intravenous drug abusers suffer from greater rates of infection than non-abusers. This suggests that chronic drug use reduces function of the immune system. However, it is difficult to make this association clearly since drug abusers typically have many risk factors for developing infections. In addition, attempts to implicate any single drug in potential effects are confounded by the multi-drug use prevalent in this population.

Some animal studies have provided data suggesting opioids do reduce immune function in a clinically relevant manner (see McCarthy et al., 2001, for review). A single dose of morphine in mice or rabbits drastically reduced reticuloendothelial system activity, phagocyte count, phagocytic index, killing properties, and superoxide anion production in polymorphonuclear leukocytes and macrophages (Tubaro et al., 1983). Morphine also increased the susceptibility of animals to fungal infection. The results suggest that there is a relationship between morphine's depression of phagocytic functions and morphine's exacerbation of infections. In a similar study morphine increased the sensitivity of mice to a strain of *Toxoplasma gondii* (Chao et al., 1990). Interestingly in this study, if the mice were made tolerant to morphine, the sensitization effect was lost. A similar protective effect of tolerance was found in pigs infected with swine herpes virus-1 (Risdaal et al., 1993).

In studies examining the human population, results vary. While one study found that survival in HIV-infected intravenous drug abusers was significantly shorter compared to those not using intravenous drugs (Rothenberg et al., 1987), more recent studies have found no difference in disease progression between the two groups (Margolick et al., 1992; Lyles et al., 1997). Based on animal studies it seems that opioid drugs, such as morphine, can reduce immune function in the whole animal, as indicated by both *in vitro* and *in vivo* studies. It is not presently clear how directly these results will trans-

late into the clinical setting or whether they will be relevant to treatment of normal individuals or of those with on-going infections and/or undergoing treatment for drug abuse, such as with methadone or naltrexone.

38.3.3. Sedative-Hypnotic Agents and Drug Abuse

Sedative-hypnotic agents are some of the most widely prescribed and used drugs in the developed world. They are also frequently drugs of abuse. Sedative-hypnotics are used to promote sleep, as their name implies, and to reduce anxiety. Their overall effect is to act as CNS depressants. We will consider the two major classes of drugs in this category, the benzodiazepines and the barbiturates. For a detailed discussion of the pharmacology of these agents, see Charney et al. (2006).

38.3.3.1. Benzodiazepines

The benzodiazepines are a group of chemically related drugs, the best-known members of which are chlordiazepoxide (Librium®) and diazepam (Valium®). There are many others with variations in properties, particularly onset of effects and duration of action. The most recognized effects of the benzodiazepines are centrally mediated and include sedation, hypnosis, decrease in anxiety, muscle relaxation and anticonvulsant effects.

38.3.3.1.1. Benzodiazepine Receptors

The best-characterized molecular target of the benzodiazepines is the GABA-A receptor (Charney et al., 2006; Burt, 2003). Each receptor, which acts as a chloride channel, is composed of five subunits. There are at least seven subunit families composed of at least 19 individual subunits. Some of the subunits undergo alternative splicing, adding to the complexity. Because of the multitude of subunits, there are many thousands of potential subunit combinations. In reality, far fewer are expressed. The most common composition of GABA-A receptors is two alpha, two beta, and one gamma subunit. Which particular subunits compose the GABA-A receptor in different regions of the brain is not well understood. Since the subunit composition determines receptor pharmacology, channel properties and intracellular localization, understanding the composition of the receptors expressed in a particular tissue or cell type is very important. Because of the multitude of possible subunit compositions and the fact that a single cell may express more than one type of GABA-A receptor, understanding the function of GABA-A receptors is a daunting task.

As mentioned above, the GABA-A receptor is a chloride channel. Binding of GABA to the receptor opens the channel to allow an inward flux of chloride ions. Benzodiazepines are modulators of this action. Benzodiazepines are thought to bind at the interface of the alpha and gamma subunits and they

do not affect receptor function unless GABA also binds to the receptor. In this case, the benzodiazepines increase the effect of GABA, leading to a greater chloride flux and a greater hyperpolarization of the cell, producing an inhibition of synaptic transmission.

A second receptor for the benzodiazepines is the peripheral benzodiazepine receptor (PBR) which is an enigmatic receptor (Gavish et al., 1999). While there has been a significant amount of work published about it, the PBR remains somewhat obscure and its physiological role is still not clear. The PBR are found primarily on mitochondrial membranes (Zavala, 1997), but are also present on cell surface membranes. In mitochondria the PBR complex has been suggested to make up the mitochondrial permeability transition pore, which plays an important role in regulation of cell survival or death (Casellas et al., 2002). The PBR has been characterized primarily by radioligand binding studies. As the name implies, the PBR was originally discovered as a binding site for benzodiazepines that was pharmacologically distinct from the central binding site and was found outside the CNS. The highest concentration of PBR is found in the adrenal gland but it has also been identified in many other peripheral organs. The pharmacology of the PBR is distinct from that of the central benzodiazepine (GABA-A) receptor in that some of the classical benzodiazepines bind to the PBR with high affinity, while others have only low affinity for the receptor. Some benzodiazepines have a high affinity for both the PBR and GABA-A receptors, while others have high affinity for only one. The clinically useful drugs all have a relatively high affinity for the central receptor.

38.3.3.1.2. Benzodiazepines and the Immune System

Knowledge of the interaction of benzodiazepines and the immune system is much less advanced compared to our understanding of interactions between opioid systems and the immune system. It is clear that the benzodiazepines have strong anti-anxiety effects and that through these actions they reduce the response to stressful situations (Zavala, 1997). This, in turn, will reduce stress-induced activation of the HPA axis and so reduce its regulatory effects on the immune system. These effects are centrally mediated, however, and can be considered indirect effects.

A direct effect of benzodiazepines on immune cells is implied by the presence of GABA-A receptors on some immune cells. Central benzodiazepine receptors form part of and regulate the activity of the GABA-A receptor. Mouse T lymphocytes and human peripheral blood mononuclear cells have been shown to express functional GABA-A receptors (Bergeret et al., 1998; Alam et al., 2006). Treatment of T cells with GABA inhibited proliferation and the effect was identified as being due to GABA-A receptors using pharmacological criteria (Tian et al., 1999). A similar study demonstrated inhibition of several proinflammatory T cell functions by GABA (Tian et al., 2004). More directly,

diazepam has been shown to alter neutrophil activity *in vivo*, supporting an effect of benzodiazepines on immune function in the whole animal (da Silva et al., 2003). In this study acute treatment with diazepam increased several measures of activity while chronic treatment increased the PMA-induced neutrophil oxidative burst but decreased neutrophil phagocytosis. There is much more to be learned in this relatively young field.

Numerous studies point to a role for peripheral benzodiazepine receptors (PBR) in regulation of immune function as well (see Covelli et al., 1998; Zavala, 1997). PBR are reported to be expressed on many cells within the immune system, with a rank order of monocytes = polymorphonuclear neutrophils > B cells, NK cells and T cells. It has been shown that benzodiazepines acting on PBR produce a stimulation of chemotaxis, the production of reactive oxygen species and cytokine production. For example, stimulation of PBR induces chemotaxis in human monocytes, an effect not produced by stimulating central benzodiazepine receptors (Ruff et al., 1985). PBR agonists reduce the ability of splenocytes and macrophages to produce an oxidative burst. Conversely, blocking PBR in human neutrophils with antibodies enhances the oxidative burst produced by stimulation with fMLP (Zavala et al., 1990, 1991). In an *in vivo* study, diazepam administration blocked an increase in superoxide anion production in response to a stressful situation, and phagocytosis by peritoneal macrophages was reduced (Salman et al., 2000). Stimulation of mouse spleen macrophages by LPS leads to the production of TNF and this effect can be inhibited by PBR agonists (Zavala et al., 1990). However, studies with human immune cells are not as clear cut and PBR agonists can exhibit bell-shaped dose-response curves, producing just the opposite effects at some concentrations (Taupin et al., 1991). In his review, Zavala concludes that stimulation of peripheral PBR has important consequences on immune cell function, but the data are not always consistent in terms of effects produced (Zavala, 1997).

Unfortunately, for reasons that are not clear, interest in studies of PBR in general, including PBR regulation of immune function has waned in recent years and the lack of progress leaves the entire issue of PBR function in the immune system cloudy. Part of the reason for decreased interest may be the finding that in many cases the benzodiazepines used clinically have been found to have weak or no activity at PBR in some systems, so the relevance to drugs currently used in the clinics is not apparent.

38.3.3.2. Barbiturates

The barbiturates are the other major group of sedative-hypnotic agents. Similar to the benzodiazepines, they are a group of chemically related drugs and there are many variations in properties, particularly onset of effects and duration of action. The most recognized effects of the barbiturates are centrally mediated and include sedation, hypnosis, decreased anxiety, and, at high doses, anesthetic properties. The mechanism of

action of the barbiturates is similar to that of the benzodiazepines in that barbiturates increase chloride conductance through the GABA-A receptor. However, there are significant mechanistic differences as well. The exact site of barbiturate action is not certain, although there is some evidence barbiturates act at the interface between the alpha and beta subunits. Gamma subunits do not have to be present in GABA-A receptors for barbiturates to produce their effects, in contrast to the benzodiazepines. In addition, barbiturates potentiate GABA actions by prolonging the periods during which channel openings occur in response to GABA, whereas benzodiazepines increase the frequency of opening bursts.

The impact of barbiturates on immune system function is even more poorly defined than the impact of benzodiazepines. The presence of GABA-A receptors on immune cells offers the possibility that barbiturates can affect immune function. However there has been little examination of this area. Early studies indicated that select barbiturates, such as thiopental, may impair oxygen radical production during phagocytosis of neutrophils (Weiss et al., 1994a; Weiss et al., 1994b), whereas most other barbiturates do not. There appear to be no other detailed studies examining barbiturate impact on immune cells, particularly on specific immune cell types. Based on the little information in the literature, the current conclusion is that most barbiturates, when used at clinically relevant doses, probably do not have a significant impact on immune function.

38.3.4. General Anesthetics

The general anesthetics are a chemically diverse group of drugs used primarily during major surgical procedures. They produce several important effects, including loss of pain perception, loss of consciousness, reduction of autonomic responses, amnesia and respiratory depression. They depress many, if not most, CNS modalities. A detailed account of their pharmacology is presented by Evers and colleagues (Evers et al., 2006).

The mechanism of action for the general anesthetics has been the subject of debate for decades. The unitary theory of anesthetic action held sway for many years and posited that all general anesthetics act by perturbing the physical properties of cell membranes. This all-encompassing and relatively vague explanation has been discarded in recent years. Current understanding is that general anesthetics depress synaptic transmission and some data indicate this is region-specific in the CNS, depending on the agent in use.

In general, there are two broad mechanisms by which the decrease in synaptic transmission is achieved by general anesthetics, either increased inhibitory neurotransmission or decreased excitatory neurotransmission. Many general anesthetics, particularly inhalation anesthetics, appear to act at GABA-A receptors, increasing the sensitivity of the receptors to GABA. This is similar to the effects of the sedative-hypnotic agents, at least at a superficial level, and it results

in increased inhibitory neurotransmission. There is evidence that general anesthetics acting through GABA-A receptors bind to a specific site or sites on the receptor, although these have not been defined in most cases. There is limited evidence that other general anesthetics may act by increasing the activation of inhibitory glycine receptors or by reducing the activity of excitatory neuronal nicotinic receptors, both actions that would produce the same end result, decreased activation of postsynaptic neurons. Several other mechanisms of general anesthetic actions are known or have been proposed, including inhibition of excitatory NMDA receptors, and activation of potassium channels leading to a greater cellular hyperpolarization (Evers et al., 2006). While much remains to be learned, the common factor in all of these mechanisms is reduction in postsynaptic neuronal excitability.

38.3.4.1. General Anesthetics and the Immune System

The impact of general anesthetics on immune system function is even less characterized than that of the opioids or the sedative-hypnotic agents. Based on the expression of GABA-A receptors by immune cells, as mentioned above, the molecular target for some of the general anesthetics is in place. The demonstration of NMDA receptors on T cells (Miglio et al., 2005) and of glycine receptors on macrophages and leukocytes (Froh et al., 2002) offers the possibility that other general anesthetics may also affect immune function. Overall, however, the information available is limited. While it is clear that anesthesia and surgery depress immune function, deciphering the role of general anesthetics in this complex situation is difficult. A number of *in vitro* studies have shown that anesthetic agents suppress a number of immune functions, including recruitment and activation of neutrophils, lymphocyte activity and NK cell activity. However, even though there are many *in vitro* studies demonstrating changes in immune cell function, there have been no studies that have shown their importance clinically and it has been suggested that in healthy people these effects are probably negligible (Levy, 2006; Galley and Webster, 2006). On the other hand, it is possible effects of general anesthetics on the immune system may be relevant in patient populations whose overall health is compromised. This question remains to be resolved.

38.4. Immunopharmacologies

This section provides a discussion of the pharmacology of the various agents that directly affect the immune system. It emphasizes their mechanism of action with a brief description of their therapeutic uses. More detailed information on their pharmacology can be found in *Goodman and Gilman's The Pharmacological Basis of Therapeutics* (Brunton et al., 2006). Immunopharmacologies can be divided into two major areas, the immunostimulants and the immunosuppressives.

38.4.1. Immunostimulating Agents

Since many diseases are associated with cellular immunodeficiency there is an important need for immunostimulants. They have potential use as vaccine adjuvants and for the treatment of cancer, human immunodeficiency viral infections and in certain other infections. The immunostimulating agents are probably best known at this time for their use in the treatment of cancer. When used for this purpose these drugs often act through more than one mechanism. For example, in addition to their ability to augment the immune system, they may have direct cytotoxic effects as well as being able to induce differentiation of the cancer cells.

38.4.1.1. Interferons

Interferons were first characterized as antiviral proteins produced by host cells. Later it was found that interferons had antiproliferative activity and also served as modulating agents for macrophages and natural killer cells.

Interferons consist of three families of protein molecules (α , β and γ) whose production can be induced in most cells by several different stimuli. Interferon- α is induced in several types of leukocytes by foreign cells, virus-infected cells, tumor cells, bacterial cells and products and virus envelopes. Interferon- β is produced in fibroblasts, epithelial cells and macrophages by viral and other foreign nucleic acids. Interferon- γ is induced in T lymphocytes by foreign antigens to which the T cells are sensitized (Ballow, 2005; Samuel, 2001). Natural killer cells also produce this interferon under certain conditions. More recent technology allows interferons to be produced by recombinant DNA techniques usually by using a genetically engineered *Escherichia coli* bacterium containing DNA coding for human interferon. Interferons first bind to specific cellular receptors and then initiate a series of intracellular events including induction of certain enzymes, inhibition of cellular proliferation and enhancement of immune activities. The effects of interferon on the immune system include increased phagocytosis by macrophages and augmentation of specific cytotoxicity by T lymphocytes. Interferon may also modulate major histocompatibility molecules, tumor-associated antigens, dendritic cells, Fc γ receptors, and intercellular adhesion molecules (ICAM-1) on tumor cells potentially making them better targets for immune recognition (Wiesemann et al., 2002; Tomkins, 1999; Krensky et al., 2005; Goldstein et al., 2003).

Interferon alpha induces remissions in 90 percent of cases of hairy cell leukemia. It is also effective against Kaposi's sarcoma and certain cases of chronic myelogenous leukemia seem to respond well. A few cases of multiple myeloma, malignant lymphoma and breast cancer have shown complete or partial responses to interferons (Goldstein et al., 2003). Interferons are seldom used as the sole agent, so it is difficult to assign exact values to effectiveness. Indeed, their effectiveness seems to be enhanced when they are used in conjunction with other cancer chemotherapeutic agents, with other cytokines or with surgery or radiation.

38.4.1.2. Interleukin-2 (IL-2)

IL-2 is a lymphokine produced by activated helper T-lymphocytes. It induces the proliferation of T cells and promotes the differentiation of lymphocytes into cytotoxic cells. IL-2 also induces interferon gamma production (Lewko and Oldham, 2003). Activation of peripheral leukocytes with the drug produces lymphokine-activated killer cells (LAK) that lyse a variety of tumor cells *in vitro*. IL-2 has been cloned in bacteria through recombinant DNA technology, thus allowing the production of large amounts. IL-2 alone or with LAK cells can cause regression of several established metastatic tumors in animals (Lewko and Oldham, 2003; Dorr, 1993).

IL-2 has been approved for the treatment of renal cell carcinoma and also has shown good activity in malignant melanoma. Both of these tumors are refractory to chemotherapy. IL-2 has also been used investigatively, both alone and in combination with LAK cells, with chemotherapy and with other biological response modifier's (BRM's) to treat a variety of different cancers (e.g., head and neck carcinoma, colorectal cancer, central nervous system cancer etc). In addition to cancer therapy, IL-2 has been used to treat patients infected with human immunodeficiency virus and it has been used *ex vivo* to generate antiviral T cells which were reinfused into patients (Lewko and Oldham, 2003; Dorr, 1993).

38.4.1.3. Immunoglobulin Intravenous Therapy (IGIV Therapy)

Immune globulin (IG) is a purified preparation of gamma globulin. It is derived from large pools of human plasma and is comprised of four subclasses of antibodies, approximating the distribution of human serum (Ballow, 2005).

IG is not absorbed to a significant extent following oral administration. Peak levels following IM administration occur in approximately 2 days. When given IV, peak levels are attained immediately but the serum IgG level drops to about 40–50% during the first week after infusion. The half-life of IgG is about 24 days in healthy adults.

Despite its widespread and long history of use its specific mechanism of action is not established. It elicits several biological and immunological responses including anti-infective, anti-inflammatory and immunomodulatory activities. The present evidence seems to be that the multiple effects work in concert with each other. Each mechanism contributes differently depending on the disease (Ballow, 2005; Shah, 2005).

IGIV is used either for antibody replacement or immunomodulation. Some of the indications as replacement therapy include general or specific immunodeficiency states e.g., hepatitis A prophylaxis, chronic lymphocytic leukemia with hypogammaglobulinemia, multiple myeloma with specific antibody deficiency, low birth weight babies at risk for infection and infants/children with HIV. It is also used as an immune modulator in conditions such as idiopathic thrombocytopenic purpura and acquired hemophilia (Krensky et al., 2005; Shah, 2005).

38.4.2. Immunosuppressive Agents

Agents that suppress the immune response have assumed an increasing importance in medicine in recent years. These agents have two important uses. One is for inhibiting organ transplant rejection. The second use of these drugs is in the treatment of autoimmune and inflammatory diseases. Major drugs used as immunosuppressives can be subdivided into several categories.

38.4.2.1. Corticosteroids

The adrenal corticosteroids have been extensively used to suppress many different aspects of the immune response. All of the corticosteroids have similar mechanisms of action. They bind to specific corticosteroid binding proteins in the cytoplasm. These complexes are then transported into the nucleus where they bind to discrete portions of the cell's DNA. This binding results in derepression of regulatory genes and the subsequent transcription of new mRNA (Rhen and Cidlowski, 2005). Steroids inhibit the consequences of the immune response. They have several different actions in this regard. One of their most important effects is to transiently alter the number of circulating leukocytes. There is a rapid increase in the number of neutrophils and a concomitant decrease in the number of lymphocytes, monocytes, eosinophils and basophils (Krensky et al, 2005).

Steroids also alter important functional activities of lymphocytes and monocytes. This effect is mainly on T lymphocytes and is at least partly due to a decrease in IL-2 production. Other proinflammatory cytokines such as IL-1 and IL-6 are also down regulated (Barnes, 2001; Krensky et al., 2005). The effect on B lymphocytes is less prominent. Steroids also profoundly impair the function of monocytes/macrophages by significantly decreasing their phagocytic ability. Glucocorticoids also increase I κ B expression, thereby curtailing activation of NF- κ B, which increases apoptosis of activated cells (Auphan et al., 1995).

Prednisone, prednisolone and other glucocorticoids are used both alone and in combination with other immunosuppressives for treatment of transplant rejection and autoimmune disorders (Barry, 1992; Krensky et al., 2005).

38.4.2.2. Calcineurin Inhibitors

38.4.2.2.1. Cyclosporine

With the discovery and development of cyclosporine, a new era in immunopharmacology was born. Cyclosporine was the first agent to affect a specific cell line of the body's immune defenses. It is suppressive mainly to T cells, in contrast to the cytotoxic agents, which affect all cell lines at the same time. Cyclosporine is the forerunner of a group of immunosuppressants that are active against specific components of the immune response.

Cyclosporine predominantly suppresses T-cell dependent immune mechanism such as those underlying transplant rejection.

tion and some types of autoimmunity. It has much less effect on humoral immunity (Krensky et al., 2005). It preferentially inhibits antigen-triggered signal transduction in T lymphocytes, inhibiting expression of many lymphokines including IL-2 and the expression of antiapoptotic proteins.

Cyclosporine binds to an intracellular protein, cyclophilin. Cyclophilins and similar binding proteins are now referred to collectively as immunophilins and their enzymatic activities are relevant to the actions of immunosuppressants such as cyclosporine and tacrolimus. This complex inhibits the phosphatase activity of calcineurin, which in turn prevents dephosphorylation and translocation of NFAT. NFAT is required to induce a number of cytokine genes, including that for interleukin-2, which serves as a T-cell growth and differentiation factor (Krensky et al., 2005; Matsuda and Koyasu, 2000). Cyclosporine also increases expression of TGF- β , which is a potent inhibitor of IL-2 stimulated cell proliferation and generation of cytotoxic T lymphocytes (Khanna et al., 1994).

It is important to point out that cyclosporine is not cytotoxic in the ordinary sense and hence does not depress bone marrow. Because it does not encourage (in fact, it suppresses) graft-versus-host immune reactions, it is especially useful in bone marrow transplants.

Cyclosporine is an important drug in preventing rejection after kidney, liver, heart and other organ transplantation (Haberal et al., 2004). Cyclosporine usually is combined with other immunosuppressives especially glucocorticoids and either azathioprine or mycophenolate mofetil and sirolimus (Krensky et al., 2005). In renal allotransplants it has improved graft acceptance in most clinics to 95 percent. In addition to its use in transplantation cyclosporine is used for the treatment of a number of autoimmune diseases. In autoimmune diseases, as might be anticipated, cyclosporine is most effective in those which are T cell mediated. These include several forms of psoriasis, rheumatoid arthritis refractive to all other therapy, uveitis, nephrotic syndrome and type I diabetes mellitus.

38.4.2.2.2. Tacrolimus

Tacrolimus is a macrolide antibiotic produced by the soil fungus *Streptomyces tsukubaensis*. It is one hundred times more potent than cyclosporine *in vitro*, but is equally as toxic if not more so. It suppresses both humoral and cell-mediated immune responses. Although chemically distinct from cyclosporine it elicits similar immunosuppressant effects.

The mechanism of action of tacrolimus is similar to that of cyclosporine at the molecular level (Krensky et al., 2005; Spencer et al., 1997). Tacrolimus exerts potent inhibitory effects on T lymphocyte activation. It binds to an intracellular protein, FKBP-12. A complex is formed which inhibits the phosphatase activity of calcineurin. This in turn prevents dephosphorylation and translocation of nuclear factor of activated T lymphocytes (NFAT) which results in inhibition of T-lymphocyte activation.

Tacrolimus is indicated for prophylaxis of organ rejection in adult patients undergoing transplantation and to treat a variety of autoimmune diseases (Fung, 2004; Krensky et al., 2005; Spencer et al., 1997).

38.4.2.3. Cytotoxic/Antiproliferative Agents

Most anti-proliferative or cytotoxic agents were originally introduced into medicine as anticancer agents. They are able to kill cells that are capable of self-replication, including both normal and neoplastic cells. In the process of responding to an antigen, immunologically competent lymphocytes are transformed from resting cells to actively proliferating cells. Thus they are susceptible to the action of the cytotoxic agents. Several different antiproliferative agents have proved highly active as immunosuppressive agents.

38.4.2.3.1. Cyclophosphamide

The alkylating agent cyclophosphamide is used in cancer chemotherapy. It was one of the first antiproliferative/cytotoxic agents used as an immunosuppressant and is a highly potent agent. It destroys proliferating cells and also appears to alkylate a portion of the DNA in resting cells. Comparatively, cyclophosphamide has a greater effect on humoral antibody responses than on cellular reactions. Its effect on cell mediated immunity is variable with some reactions are inhibited while others are augmented. The inhibition is due to its effects on T suppressor lymphocytes (Tew et al., 2001). Cyclophosphamide has been used to prevent transplant rejection especially in developing countries as a result of its low cost and ready availability. In relatively small doses, cyclophosphamide is also effective in the treatment of some autoimmune disorders such as the childhood nephrotic syndrome, severe systemic lupus erythematosus and Wegener's granulomatosis (Neuhaus et al., 1994; Valeri et al., 1994).

38.4.2.3.2. Azathioprine

Azathioprine is a prodrug in that it is slowly converted in the body to mercaptopurine. This reaction can occur in a nonenzymatic fashion with the aid of glutathione or other sulfhydryl compounds. Perhaps it is this attribute that makes azathioprine superior to mercaptopurine as an immunosuppressant. After conversion to 6-mercaptopurine, its mechanism of action is similar to other purine antimetabolites. It interferes with nucleic acid synthesis through enzyme inhibition and it may be incorporated into DNA after conversion to the nucleotide form (Hande, 2001). Therefore, its action in suppression of the growth of lymphoid cells is not selective. Although both cell-mediated and humoral responses are suppressed it does appear to have a preferential affect to inhibit T cell responses. Azathioprine has been a mainstay drug in all types of transplantation but especially in renal allografts (Hande, 2001). In recent years its use has declined as it is being replaced by mycophenolate mofetil which seems to be safer and more

effective. It is indicated as an adjunct for prevention or organ transplant rejection and in severe rheumatoid arthritis (Hong and Kahan, 2000; Krensky et al., 2005).

38.4.2.3.3. Methotrexate

Methotrexate is a folic acid analog. It inhibits folic acid synthetic pathways and DNA synthesis (Bannwarth et al., 1994). Methotrexate is widely used in the treatment of breast and other cancers. Methotrexate has recently gained favor for, and is approved for, the treatment of rheumatoid arthritis in adults who have severe active classical rheumatoid arthritis (O'Dell, 2004). It is also used to treat psoriasis and graft vs host disease.

38.4.2.3.4. Mycophenolate Mofetil

Mycophenolate mofetil is the 2-morpholinoethyl ester of mycophenolic acid (MPA). It is a prodrug that is rapidly hydrolyzed to the active form, mycophenolic acid. Mycophenolic acid is a selective, uncompetitive and reversible inhibitor of inosine monophosphate dehydrogenase (IMPDH). IMPDH is an important enzyme in the *de novo* pathway of purine nucleotide synthesis. This pathway is very important in B and T lymphocytes for proliferation. Other cells can use salvage pathways. Therefore MPA inhibits lymphocyte proliferation and functions. The mofetil ester is first converted to MPA which then is metabolized to an inactive glucuronide (Allison and Eugui, 2000). MPA has a half-life of about 16 hours (Fulton and Markham, 1996).

Mycophenolate mofetil has replaced azathioprine as the major antiproliferative agent used to prevent transplant rejection. It is usually used in combination with glucocorticoids and a calcineurin inhibitor (Mele and Halloran, 2000).

38.4.2.3.5. Sirolimus

Sirolimus is a macrocyclic lactone produced by the bacteria *Streptomyces hygroscopicus*. Like the calcineurin inhibitors cyclosporine and tacrolimus its mechanism of action involves formation of a complex with an immunophilin, in this case, FKBP-12. Unlike cyclosporine and tacrolimus, sirolimus does not affect calcineurin activity but binds to and inhibits the mammalian kinase, target of rapamycin (mTOR). mTOR is a key enzyme in cell-cycle progression. When inhibited this kinase blocks cell cycle progression at the G1 to S phase transition (Dumont and Su, 1996; Sehgal, 2003).

Sirolimus is used for the prophylaxis of organ transplant rejection in combination with a calcineurin inhibitor and glucocorticoid. In patients at high risk for nephrotoxicity it has been combined with glucocorticoids and mycophenolate to avoid permanent renal damage (Kahan and Camardo, 2001).

38.4.2.3.6. Minocycline

Minocycline is a tetracycline antibiotic. It is also an emerging anti-inflammatory agent. It has been used experimentally and in clinical trials for the treatment of Huntington's dis-

ease, Parkinson's disease, multiple sclerosis, AIDS, ALS, and Alzheimer's disease. Minocycline has antiapoptotic effects and is a metalloproteinase inhibitor (Traynor et al., 2006; Yong, 2004; Zink et al., 2005).

38.4.2.4. Antibodies

38.4.2.4.1. Antilymphocyte Antibodies

The production of antisera against a cell type is one of the oldest effective methods of achieving a specific immune action. These antibodies can be divided into two groups: polyclonal antisera that react with multiple antigenic determinants or epitopes and monoclonal antibodies that are directed at only a single epitope.

38.4.2.4.2. Antithymocyte Globulin

Antilymphocyte globulin is a polyclonal antibody that is prepared by immunizing rabbits with human thymocytes (Regan et al., 1999). It contains cytotoxic antibodies that bind to several antigens on the surface of human T lymphocytes. The antibodies deplete circulating lymphocytes by direct cytotoxicity and block lymphocyte function by binding to cell surface molecules involved in the regulation of cell function (Krensky et al., 2005). Clinically this antisera is used primarily to treat acute renal transplant rejections in combination with other immunosuppressants. It is also used for acute rejection of other types of organ transplants and for prophylaxis of rejection (Wall, 1999). This reagent is not specific for T cells and will cross react with other cell types.

38.4.2.4.3. Muromonab-CD3 (Murine Monoclonal Antibody, Anti-CD3)

Anti-CD3 is a monoclonal antibody directed against the ϵ chain of CD3, a trimeric molecule adjacent to the T-cell receptor on human T lymphocytes (Krensky et al., 2005). It functions as an immunosuppressant, blocking graft rejection during organ transplantation. T cell function is blocked by interfering with CD3, a molecule in the membrane of these cells. CD3 is associated with antigen recognition, proliferation and signal transduction. The number of circulating CD3 positive, CD4 positive and CD8 positive T cells is decreased within minutes of administration of muromonab-CD3. Complement apparently is not involved in this reaction and T cell removal probably results from phagocytic activity of the reticuloendothelial system that follows opsonization by the monoclonal antibody. This is believed to play a major role in the clinical efficacy of this antibody. Recent evidence indicates that other mechanisms also play a role. There is evidence that this antibody induces apoptosis or programmed cell death in certain T cells. A third mechanism is that this antibody may mediate T cell cytotoxicity by inter-T cell bridging (Hooks et al., 1991; Roitt, 1993; Wilde and Goa, 1996). Monoclonal antibodies like Anti-CD3 have the advantage over polyclonal antibodies of being more selective in their action and of being

able to be more precisely administered. In addition they can be more accurately quantitated.

Anti-CD3 is mainly indicated in the treatment of acute allograft rejection in renal transplant patients (Wilde and Goa, 1996; Woodle et al., 1999). Repeated use of muromonab-CD3 can result in the immunization of the patient against the mouse determinants of the antibody rendering it ineffective. Anti-CD3 also produces significant toxicity.

38.4.2.4.4. Daclizumab and Bacluzimab

Daclizumab and bacluzimab are monoclonal antibodies humanized to minimize the occurrence of anti-antibody responses and are mutated to prevent binding to FcRs (Friend et al., 1999). They were developed with the rationale that they could induce selective immunomodulation in the absence of toxicity associated with conventional anti-CD3 monoclonal antibody therapy. Daclizumab and basiliximab are produced by recombinant DNA technology. These antibodies bind with high affinity to the alpha subunit of IL-2 receptor present on the surface of activated, but not resting T lymphocytes and block IL-2 mediated T-cell activation events (Chapman and Keating, 2003; Krensky et al., 2005). Daclizumab has a somewhat lower affinity than does basiliximab (Krensky et al., 2005). These drugs are recommended for prophylaxis of acute organ rejection in adult patients usually as part of combination therapy with glucocorticoids, a calcineurin inhibitor and azathioprine and/or mycophenolate.

38.4.2.4.5. Infliximab

Infliximab is a chimeric anti TNF- α monoclonal antibody containing a human constant region and a murine variable region. It binds with high affinity to TNF- α and prevents the cytokine from binding to its receptors. It is used to treat rheumatoid arthritis and inflammatory bowel disease (Louie et al., 2003).

Summary

Immune system function is regulated or altered by a diverse array of factors. In this chapter we have summarized three seemingly disparate aspects of this array to demonstrate how widespread and varied this regulation may be. The immune system can be affected by the autonomic nervous system, various agents acting on the CNS, including opioid drugs, the sedative-hypnotic agents (the benzodiazepines and barbiturates) and the general anesthetics, and various immunosuppressive and immunostimulating agents. This emphasizes both the complexity of immune system regulation and the sometimes unexpected nature of drug interactions with the immune system. Some of these drugs, which have not been considered as immunotherapeutic agents, offer the possibility of being exploited for their ameliorative effects on diseases affecting the immune system.

Review Questions/Problems

- Muscarinic receptor activation can be blocked by the presence of**
 - neostigmine
 - nicotine
 - trimethaphan
 - botulinum toxin
 - atropine
- Botulinum toxin acts by**
 - blocking Ca^{++} influx into cholinergic nerve endings
 - hydrolyzing the proteins required for docking of the synaptic vesicle with the presynaptic membrane
 - inhibiting choline uptake
 - inhibiting choline acetyltransferase
 - blocking nicotinic receptors
- The initial action by which cocaine increases heart rate is by**
 - blocking the degradation of norepinephrine
 - increasing the release of norepinephrine
 - stimulating autonomic ganglia
 - stimulating α_1 adrenergic receptors
 - preventing the reuptake of norepinephrine
- Dopamine synthesis is increased by activation of**
 - dopamine β -hydroxylase
 - L-aromatic amino acid decarboxylase
 - tyrosine hydroxylase
 - monoamine oxidase
 - choline acetyltransferase
- The effect of amphetamine on blood pressure will be blunted if an animal has first been treated with**
 - reserpine
 - terbutaline
 - trimethaphan
 - physostigmine
 - botulinum toxin
- The ability of phenylephrine to increase vagal tone would be blunted in the presence of**
 - propranolol
 - terbutaline
 - physostigmine
 - cocaine
 - prazosin
- The vasoconstrictive effect of norepinephrine on the movement of blood through a capillary bed will be enhanced by the concurrent presence of**
 - prazosin
 - metoprolol

- c. isoproterenol
 - d. reserpine
 - e. cocaine
- 8. Expression of mu and kappa opioid receptors has been found on**
- a. T cells
 - b. B cells
 - c. lymphocytes
 - d. peripheral blood mononuclear cells
 - e. all of the above
- 9. The end result on immune system function of treatment with opioid drugs, such as morphine, is**
- a. depression of immune function
 - b. stimulation of immune function
 - c. increased phagocytic activity
 - d. decreased viral replication
 - e. decreased expression of MOP and KOP receptors
- 10. A binding site (receptor) for both benzodiazepines and barbiturates can be found on the**
- a. mu opioid receptor
 - b. NMDA receptor
 - c. GABA-A receptor
 - d. peripheral benzodiazepine receptor
 - e. GABA-B receptor
- 11. Peripheral benzodiazepine receptors are found primarily**
- a. at synapses with GABA-A receptors
 - b. as heterodimers with opioid receptors
 - c. in the CNS, a paradox
 - d. on mitochondrial membranes
 - e. on macrophages
- 12. A common factor in the proposed mechanisms of action for general anesthetics is**
- a. a reduction in postsynaptic excitability
 - b. increased activity at excitatory neurotransmitter synapses
 - c. perturbation of the physical properties of cellular membranes
 - d. increased sympathetic nervous system activity
 - e. blockade of chloride channel function
- 13. Current research makes it clear that the opioids, sedative-hypnotic agents, and general anesthetics, as used clinically, have a major impact on immune system function**
- True/False
- 14. Which of the following statements best describes the mechanism of action of the interferons?**
- a. selectively stimulate T lymphocytes
 - b. bind to specific cellular receptors resulting in inhibition of proliferation
 - c. bind to cyclophilin with resulting inhibition of NFAT translocation to the nucleus
 - d. inhibit T cell DNA polymerase
 - e. are antimetabolites and are incorporated into DNA
- 15. A rapid decrease in the number of lymphocytes, monocytes and eosinophils best describes the mechanism of action of**
- a. basiliximab
 - b. mycophenolate mofetil
 - c. tacrolimus
 - d. corticosteroids
 - e. immunoglobulin
- 16. Which of the following statements best describes the mechanism of action of cyclosporine? It**
- a. binds to and inhibits m-TOR
 - b. increases apoptosis of T lymphocytes
 - c. binds to cyclophilin and inhibits calcineurin
 - d. binds to steroid nuclear receptors
 - e. inhibits tyrosine kinase phosphorylation of certain G protein coupled receptors
- 17. The major clinical use for muromonab-CD3 is**
- a. acute leukemia
 - b. rheumatoid arthritis
 - c. renal cancer
 - d. HIV infections
 - e. to prevent transplant rejection
- 18. Sirolimus, in contrast to tacrolimus**
- a. is used in cancer chemotherapy
 - b. is a purine antimetabolite
 - c. binds to steroid nuclear receptors
 - d. does not inhibit calcineurin
 - e. inhibits reverse transcriptase
- 19. Infliximab is**
- a. an antibody against the CD3 receptor
 - b. a humanized anti-TNF α monoclonal antibody
 - c. a polyclonal antibody
 - d. a monoclonal antibody to the HER2 oncogene
 - e. an inhibitor of calcineurin
- 20. Name three clinical uses for IGIV.**

39.1. Introduction

The neurodegenerative disorders, which include Amyotrophic Lateral Sclerosis (ALS), Alzheimer Disease (AD), Parkinson Disease (PD), and Huntington Disease (HD), are clinically heterogeneous. Medications can ameliorate some symptoms, but none reverse the relentless progression of the illnesses. The past several decades have seen a dramatic increase in the understanding of the complex pathophysiology underlying the diseases. Overlapping features at the cellular level provide clues for targets of therapeutic interventions. While the disorders can now be studied using *in vitro* and animal models, they have posed a particular challenge because of their complex biochemistry, pathology and lack of mechanism based treatments. There are still few unequivocal neuroprotective agents, and we await the major breakthrough that will provide truly meaningful clinical improvement. Until then, numerous symptomatic therapies can improve the quality of life of those suffering from neurodegenerative diseases. This chapter outlines the current strategies for the use of symptomatic therapies and the development of neuroprotective treatment for neurodegenerative disorders.

39.1.1. Overview of Mechanism

Progressive and premature neuronal cell death is the common feature among the neurodegenerative disorders. ALS involves progressive degeneration of the motor neurons in the brain and spinal cord, AD shows selective neuron degeneration in the hippocampus and cerebral cortex, PD is caused by degeneration of pigmented dopaminergic neurons in the substantia nigra, and HD has selective neuron loss in the striatum

and cortex. It is increasingly recognized that the clinical syndromes may overlap, with features of two or more disorders co-existing. For instance, ALS and dementia, or ALS, parkinsonism and dementia may occur together in the same family or in an individual. Similarly, the disorders have common pathological findings at the cellular level. While the mechanisms that lead to neuronal degeneration are still being sought, in general, it is thought that neurodegenerative diseases are caused by a combination of events including age-associated, genetic and environmental factors in varying proportions (Rowland and Shneider, 2001; Koo and Kopan, 2004). All cases of HD, but only rare cases of ALS and AD are due to single genetic mutations. In the sporadic forms, complex genetic interactions may render an individual susceptible to some, as yet unknown, environmental exposure, with the combination necessary to initiate the disease. Whatever the cause, be it genetic, environmental or some combination of the two, there is set in motion a cascade of events at the cellular level that ultimately results in cell death. Animal models of the genetic forms of the disorders have helped elucidate some of the underlying molecular mechanisms that contribute to neuronal demise. Common processes among the neurodegenerative diseases include oxidative stress, excitotoxic injury, altered metal homeostasis, aberrant protein aggregation, mitochondrial injury, apoptosis, and inflammation (Bossey-Wetzel et al., 2004; Andersen, 2004; Ross and Poirier, 2004). Once the etiologies of individual disorders are identified, more effective treatments will surely follow. Until then, a major goal is to identify therapies that slow the course of the illnesses by targeting cellular changes that occur after the inciting event.

39.1.2. Overview of Animal Models

The inherited forms of neurodegenerative diseases have been utilized in the development of animal models. Rodent models created using transgenic and gene targeting technologies (Deng and Siddique, 2000) now provide the opportunity to better study disease pathology and screen potential therapeutic

agents. The advent of the ALS mouse model is one example of the progress that has resulted from this technology. A mutation in the gene encoding the enzyme copper–zinc superoxide dismutase (SOD1) on chromosome 21 was identified as a causative mutation in one form of familial ALS (Rosen et al., 1993). The first mutant transgenic mouse line was created by over expressing high levels of mutant SOD 1 (G93A). This mouse developed a phenotypic and pathologic condition similar to human familial and sporadic ALS (Gurney et al., 1994). The murine model of ALS has since been used to screen a variety of therapeutic agents. Riluzole, the only approved agent for ALS, yielded positive results in the model that correspond very closely to the modest benefit in human clinical trials (Gurney et al., 1996, 1998).

Similarly, mouse models have been created for other neurodegenerative diseases. Transgenic mouse models of AD express mutations in the amyloid precursor protein (APP), presenilin genes, or a combination of the two (German and Eisch, 2004). Insight into the molecular mechanisms of dopaminergic cell death in PD have come from the study of 6-hydroxydopamine (6-OHDA) and 1-methyl 1–4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) animal models (Dawson, 2000). Discovery of genes linked to familial PD have also provided the opportunity to generate animal models that better recapitulate the phenotypic and pathologic features of PD. Similarly, animal models have been created for HD through utilization of the CAG triplet expansion in the HD gene. Homozygous and heterozygous knockout mice did not produce the phenotypic or pathologic features of HD, but transgenic mice models of HD did produce a progressive neurological phenotype that resembles features of HD and has improved the understanding the disease process (Deng and Siddique, 2000).

Many of the past and current therapeutic trials have been aimed at slowing neurodegenerative processes detected in animal models. While it is evident that the models of human diseases have played an essential role in understanding the mechanisms involved in neurodegeneration and in developing therapeutic strategies, the translation of findings in animal models to human therapeutics has been fraught with difficulty. Ten years after the approval of riluzole and following numerous clinical trials based on findings in the model, we still await the second unequivocally positive trial in ALS. Humans are more complex than rodents; the murine models may best be used for establishing the scientific justification for testing a potential agent, with the knowledge that findings in the laboratory, as yet, cannot provide certain hope of success in human trials.

39.2. Disease-Specific Therapy

In certain disorders, such as AD and PD, neurodegeneration leads to deficiencies in specific neurotransmitters. Therapy has been targeted at replacing or increasing levels of the deficient neurotransmitter in patients. Disease specific therapy of this

his type does not alter the underlying progression of neurodegeneration, but may improve symptoms, at least temporarily.

39.2.1. Alzheimer's Disease

Changes in the cholinergic system in AD were first studied by Whitehouse et al. (1981), who found atrophy of cholinergic nerve cells in the substantia innominata. It was thought that replacing or increasing acetylcholine in patients with AD could stabilize cholinergic transmission. The cholinergic hypothesis of AD has been the basis of many research efforts and the accumulated evidence has launched the development of a variety of compounds that improve cholinergic neurotransmission (Lanctot et al., 2003; Scarpini et al., 2003). Currently, the cholinergic deficiency is considered to be a secondary event resulting from nerve cell death due to other causes (Albers and Beal, 2000).

39.2.1.1. Cholinesterase Inhibitors

Cholinesterase inhibitors, developed with the goal of stabilizing cholinergic transmission, block the enzyme that degrades acetylcholine in the synaptic cleft and lead to increased levels of acetylcholine in the brain. There are four types of cholinesterase inhibitors currently available in the United States: tacrine, donepezil, rivastigmine and galantamine (Table 39.1). Tacrine, donepezil and galantamine are selective inhibitors of acetylcholinesterase. Galantamine is an allosteric ligand of the nicotinic acetylcholine receptor and is believed to increase the presynaptic release of acetylcholine and prolong postsynaptic neurotransmission (Greenblatt et al., 1999; Scott and Goa, 2000). Donepezil is a piperidine derivative that noncompetitively and reversibly blocks acetylcholinesterase. Rivastigmine is a slow reversible inhibitor of acetylcholinesterase.

Individually, the cholinesterase inhibitors improve memory in patients with AD. There have been no head-to-head comparisons made of the drugs to determine whether one is more effective than the others and no trials of agents in combination. The main known differences are the side effect profiles, titration schedules and the dosing regimens (Table 39.1). The most common side effects of treatment with cholinesterase inhibitors are gastrointestinal and include nausea, vomiting and diarrhea. A meta-analysis of the efficacy and safety of these agents revealed that despite many clinical studies showing

TABLE 39.1. Disease specific and neuroprotective therapy in Alzheimer disease.

Medication	Dosage
<i>Cholinesterase inhibitor</i>	
Tacrine (Cognex)	20–40mg QID
Donepezil (Aricept)	5–10mg QD
Rivastigmine (Exelon)	3–6mg BID
Galantamine (Razadyne)	8–12mg BID
<i>NMDA antagonist</i>	
Memantine (Namenda)	10mg BID

short-term benefit, there is insufficient evidence to conclude long term efficacy (Lanctot et al., 2003).

39.2.2. Parkinson's Disease

As in AD, knowledge of the neurotransmitter deficiency underlying PD, in this case dopamine, has been the basis for the development of therapy. Early studies showed that cerebral dopamine was concentrated in the striatum and that levodopa, the precursor to dopamine, could reverse the akinetic effects of the dopamine-depleting agent reserpine in experimental animals (Carlsson et al., 1957, 1958). Eventually, the identification of striatal dopamine depletion as a key neurochemical finding in parkinsonian brains lead to treatment with levodopa in humans and to the subsequent advent of compounds that mimic the effects of dopamine or prolong its action (Table 39.2).

39.2.2.1. Levodopa

Levodopa is the most effective drug for the symptomatic management of PD. Levodopa, which usually produces an excellent initial response in alleviating the motor symptoms of PD, is particularly effective for bradykinesia and tremor (Fahn, 2000). However, side effects such as motor fluctuations and dyskinesias may limit its long-term usefulness for individual patients (Fahn, 2000; Jankovic, 2000). Up to 50% of all patients treated for 5 years or more develop instability in their motor response (Koller et al., 1999; Schrag and Quinn, 2000). As a consequence, levodopa is usually given later in PD, particularly in younger patients who may require many years of anti-Parkinson therapy. In this group, dopa-sparing agents (see below) are usually prescribed until symptoms begin to interfere with independence. Levodopa is often used

as the first drug of choice in the elderly, in whom low dose monotherapy is preferable to avoid side effects, and who may not be expected to develop motor fluctuations after years of therapy due to their already advanced age. Immediate and controlled release preparations of levodopa are available.

Carbidopa, a peripheral dopa decarboxylase inhibitor, enhances the therapeutic benefits of levodopa (Opacka-Juffrey and Brooks, 1995). Levodopa is converted to dopamine by dopa decarboxylase, an enzyme that functions both inside and outside the brain. Peripherally produced dopamine directly stimulates the medullary vomiting center, which is not protected by a blood brain barrier, producing anorexia, nausea and vomiting. Carbidopa in doses less than 150 mg per day does not enter the brain and so blocks only the peripheral metabolism of levodopa (Cedarbaum et al., 1986). Co-administration of carbidopa and levodopa therefore has two main effects: It reduces levodopa-related gastrointestinal side effects, and insures that the majority of levodopa is converted to dopamine in the brain where it is needed. Seventy-five mg of carbidopa per day is necessary to completely block peripheral dopa decarboxylase activity. Additional doses can be given to those who are particularly sensitive to levodopa-induced nausea. Other major side effects of levodopa therapy include orthostatic hypotension, chorea, dystonia, myoclonus, akathisia and hallucinations. Studies have not yet shown conclusively whether levodopa alters the underlying rate of neurodegeneration (Fahn and The Parkinson Study Group, 2005).

39.2.2.2. Catechol-O-methyltransferase Inhibitors

Another strategy to enhance dopamine response utilizes the inhibition of catechol-O-methyltransferase (COMT), which metabolizes dopamine once it has been converted from levodopa either in or outside the brain. Agents that block the degradation of dopamine by inhibition of COMT effectively prolong the half-life of dopamine and may increase its peak concentration. The two currently available COMT inhibitors, entacapone (Rinne et al., 1998; Holm and Spencer, 1999) and tolcapone (Kurth and Adler, 1998; Tolcapone Study Group, 1999), reduce motor off time when given with levodopa, but the efficacy of the two drugs has not been directly compared. Tolcapone has a theoretical advantage over entacapone in that it inhibits both peripheral and central COMT, and it has a longer duration of action necessitating administration only three times per day. However, tolcapone can cause explosive diarrhea and abnormal liver function. Fulminant liver failure has occurred, albeit rarely, and therefore frequent monitoring of liver function is necessary in those prescribed tolcapone (Assal et al., 1998). Entacapone usually does not cause diarrhea or abnormal liver function and can be administered with levodopa up to eight times a day.

39.2.2.3. Dopamine Agonists

Dopamine agonists exert their effect by activating dopamine receptors and bypassing the presynaptic synthesis of

TABLE 39.2. Disease specific therapy in Parkinson disease.

Medication	Dosage
<i>Dopamine precursor</i>	
Levodopa	300–3,000 mg per day
<i>Dopa decarboxylase inhibitor/dopamine precursor</i>	
Carbidopa/levodopa	25 mg/300 mg – 200 mg/2,000 mg per day
<i>Dopamine agonist</i>	
Bromocriptine	10–30 mg TID
Pergolide	1 mg TID
Ropinirole	3–8 mg TID
Pramipexole	0.5–1.5 mg TID
Cabergoline	2–10 mg per day
<i>COMT inhibitor</i>	
Entacapone	200–400 TID—6×/day
Tolcapone	100–200 TID
<i>NMDA antagonist/anticholinergic</i>	
Amantadine	100–300 per day
<i>Anticholinergic</i>	
Trihexyphenidyl	2 mg TID
Benzotropine	1–4 mg QD
<i>MAO inhibitor</i>	
Selegiline	5 mg BID

dopamine. They are often used as part of a dopa-sparing strategy, in which agonists are prescribed early in PD, postponing the need for levodopa and the motor complications associated with exogenous dopamine administration. Activation of the dopamine-2 (D2) receptors is important in mediating the motor effects of dopamine agonists, but to achieve optimal physiologic and behavioral responses, both D1 and D2 receptors must be stimulated (Jenner, 1997; Brooks, 2000).

Bromocriptine was the first dopamine agonist developed followed by pergolide. Pergolide does not require endogenous dopamine for its pharmacological effect, possibly because it activates both D1 and D2 receptors whereas bromocriptine stimulates D2 and inhibits D1 receptors (Perachon et al., 1999). Pergolide is a more potent inhibitor of prolactin secretion and it has a half-life three times longer than bromocriptine. An early study showed that these two medications have similar efficacy in PD (LeWitt et al., 1983), but more recent data suggests that pergolide may be more effective (Pezzoli et al., 1994). Both agents should be increased slowly to prevent orthostatic hypotension and gastrointestinal side effects. Because the compounds are ergot derivatives, they may rarely be associated with retroperitoneal or pericardial fibrosis, including cardiac valvular disease (Van Camp et al., 2004).

In 1997, two additional dopamine agonists, ropinirole and pramipexole, were approved. These agents are nonergolines and therefore may carry a lower risk of ulcerative, vasoconstrictive and fibrotic complications (Shaunak et al., 1999). Pramipexole has been promoted as a D3 agonist (Bennett and Piercey, 1999), but a study that measured the affinities of bromocriptine, pramipexole, pergolide, and ropinirole for human recombinant dopamine D1, D2, and D3 receptors found that all four compounds had high affinity for the D3 receptor (Perachon et al., 1999). The observation that D3 receptors are located primarily in the mesolimbic system may explain the possible antidepressant effect of pramipexole and ropinirole (Corrigan et al., 2000), but may also explain the occurrence of hallucinations noted particularly with higher doses of dopamine agonists.

Pramipexole has been shown to be safe and effective when used as monotherapy early in PD (Parkinson Study Group, 1997, 2000) and in mild to moderate PD (Shannon et al., 1997). Ropinirole has also been shown to be effective in early PD (Rascol et al., 1998; Korczyn et al., 1999). In later stages of PD, dopamine agonists are usually prescribed with levodopa to achieve optimal therapeutic effects and to help moderate the motor fluctuations associated with levodopa (Pinter et al., 1999). Possible side effects of all dopamine agonists include nausea, peripheral edema, somnolence and hallucinations. Pramipexole has also been associated with compulsive behavior (Driver-Dunckley et al., 2003).

39.2.2.4. Anticholinergic Agents

The manipulation of nondopaminergic neurotransmitters can also be used as disease specific therapy in PD. Anticholinergic agents, the first effective therapy for PD, having been pre-

scribed by Charcot in the nineteenth century, are particularly helpful in tremor reduction. The exact mechanism of anticholinergic medications in PD remains unclear. They likely counteract an imbalance between striatal dopamine and acetylcholine that results from degeneration of dopaminergic neurons (Katzenschlager et al., 2003). Medications with anticholinergic properties include amantadine, benztropine and trihexyphenidyl, among others. Amantadine may be the most commonly used anticholinergic medication in PD. In addition to its anti-cholinergic properties, amantadine promotes the release of dopamine and blocks the N-methyl-D-aspartate (NMDA) receptor, which may relieve levodopa-induced dyskinesias. Benztropine has anticholinergic properties and also blocks the reuptake of dopamine.

A meta-analysis of nine double-blind cross-over trials found that anticholinergic therapy is effective as monotherapy or as an adjunct to other anti-Parkinson drugs (Katzenschlager et al., 2003). There have been no studies comparing differences in efficacy and tolerability among anticholinergic medications. The most common side effects include dry mouth, constipation, and urinary hesitancy. These agents may occasionally exacerbate narrow angle glaucoma. Neuropsychiatric and cognitive adverse effects limit their use in the elderly.

39.3. Neuroprotective Therapy

A neuroprotective agent alters the underlying pathophysiology of a disease and therefore delays the onset or slows the progression of neurodegeneration. Much of the current research into the treatment of neurodegenerative diseases focuses on neuroprotective therapy; agents are being tested that impact processes identified at the cellular level.

Glutamate is a major excitatory neurotransmitter in the central nervous system. Theoretically, increased glutamatergic neurotransmission may lead to excitatory neurotoxicity or excitotoxicity. The only two currently approved neuroprotective agents in the United States, riluzole for ALS and memantine for AD, may act to prevent glutamatergic excitotoxicity.

39.3.1. Riluzole

Riluzole, which may block the presynaptic release of glutamate, was initially developed as an anti-epileptic medication. However, after evidence of potential excitotoxicity in ALS began to accumulate, riluzole was tested as a neuroprotective agent. It was approved for use in ALS after two double-blind placebo controlled trials showed modest improvement in survival from 3 to 3.25 years (Bensimon et al., 1994; Lacomblez et al., 1996). Post hoc analyses revealed that patients who took riluzole had a slight prolongation in the time to progress from mild to severe disability; however, this effect was not apparent to patients, family or physicians. A meta-analysis of four randomized controlled trials indicated that Riluzole 100mg per day prolongs survival by approximately 2 months (Miller

et al., 2002). Nausea, fatigue, vertigo, and somnolence are the most common side effects of riluzole. Serum transaminase elevations may also occur but rarely to levels that are clinically meaningful.

In a survey of 559 ALS patients from ten centers that was conducted following the approval of riluzole in the U.S., only 49% of patients had taken riluzole even though 90% knew about it (Bryan et al., 1997). The reasons for not taking riluzole included perceived lack of benefit (45%), expense (31%), opinion of the ALS physician (23%), risk of side effects (14%) and the opinion of family and friends (10%). Thirty-four percent of patients discontinued riluzole due to lack of benefit, expense or adverse effects. Among the centers surveyed, the probability of a patient taking riluzole varied from 18–75%. Independent risk factors that significantly influenced the probability of taking riluzole included encouragement or discouragement by the ALS physician and Medicare coverage (no pharmaceutical coverage). This study points out that the personal cost to the patient and the encouragement from the physician are major factors determining who takes riluzole; the decision is influenced by whether or not riluzole is included on drug formularies (Gordon and Mitsumoto, 2006; Ringel and Woolley, 1999). In Europe, riluzole is approved for use in ALS and the health systems cover the cost. Consequently, almost all Europeans with ALS take riluzole (Bradley et al., 2004; Walley, 2004). Riluzole use may increase in the U.S. after institution of the new Medicare medication coverage plan in early 2006.

Once riluzole was shown to be effective for ALS and excitotoxicity was thought to be a component of neurodegeneration in general, studies of riluzole began in PD, HD and AD. The neuroprotective effects of riluzole have been shown in the 6-OHDA and MPTP models of PD (Barneoud et al., 1996; Benazzouz et al., 1995). In a small human trial, riluzole reduced levodopa-induced dyskinesias (Merims et al., 1999). In a separate pilot trial, riluzole extended the “on” state compared to placebo, but the difference was not statistically significant. A placebo-controlled trial in patients with HD showed that riluzole ameliorated chorea intensity (Huntington Study Group, 2003). Riluzole is now being evaluated in phase II clinical trials in AD (Hurko and Walsh, 2000) and in phase III trials in PD (Braz et al., 2004). Large trials with adequate power are still needed to determine whether riluzole is neuroprotective in disorders other than ALS.

39.3.2. Memantine

Memantine, a non-competitive NMDA antagonist, has medium affinity for the phencyclidine binding site of the NMDA receptor. Memantine may block glutamate mediated excitotoxicity, but it leaves the activation of the NMDA receptor during physiological neurotransmission unchanged (Molinuevo et al., 2004). Two randomized placebo controlled clinical trials showed positive effects in later stages of AD (Reisberg et al., 2003; Tariot et al., 2004). These studies led to

the approval of memantine for the treatment of moderate and severe AD. Additional clinical data are needed to determine whether memantine can be used as monotherapy or combination therapy in early AD. Common side effects include headache, dizziness, and confusion. Initial pilot trials have already been conducted in HD and PD (Beister et al., 2004; Merello et al., 1999) and are planned in ALS.

39.3.3. Selegiline

Selegiline (Deprenyl) is a monamine oxidase (MAO) inhibitor used in PD. In doses under 10 mg per day, selegiline irreversibly binds MAO-B, preventing the enzyme from degrading dopamine, but does not inhibit MAO-A, thereby avoiding the potential hypertensive crisis, or the “cheese effect,” seen with inhibitors of both MAO-A and MAO-B (Yamada and Yasuhara, 2004). The DATATOP Study (Deprenyl and Tocopherol Antioxidative Therapy of Parkinsonism) conducted in 800 patients with early untreated PD, aimed to assess the neuroprotective effects of selegiline 10 mg/day, alpha tocopherol (vitamine E) 2,000 IU/day or a combination of the two (Parkinson Study Group, 1989, 1993, 1998). After a mean follow up of 14 ± 6 months, 154 of 399 selegiline-treated subjects reached the end point, or the time to disability requiring levodopa therapy, compared to 222 of 401 subjects who did not receive selegiline. The projected median length of time to reach the end point was 9 months longer in the selegiline-treated group than in the groups treated with placebo or tocopherol. However, waning effects of selegiline after the first year coupled with slight but significant improvement in motor performance after initiation of selegiline have been used as an argument in favor of a predominantly symptomatic rather than neuroprotective effect. Data from other reports are also conflicting. Several studies suggest that it may exert some sort of protective effect, possibly by a mechanism other than MAO inhibition (Mytilineou et al., 1997, 1998; Maruyama et al., 1997). One study detected no deterioration after washout in *de novo* patients initially treated with selegiline (Palhagen et al., 1998), but most studies have concluded that while selegiline can delay the need for levodopa therapy, this does not translate into meaningful long term therapeutic benefits (Brannan and Yahr, 1995). Furthermore, selegiline does not appear to prevent the development of levodopa-induced motor fluctuations and dyskinesias (Parkinson Study Group, 1996). Further research is needed to fully define the mechanism of action of selegiline in PD, and to clarify its role as a neuroprotective agent.

39.4. Symptomatic Therapy

Even though neurodegenerative diseases still have no cure, specific symptoms may be amenable to medical treatment (Table 39.3). While few randomized clinical trials of symptomatic therapy have been performed in individual neurodegenerative

TABLE 39.3. Symptomatic therapy in neurodegenerative diseases.

Symptom	Management	Dosage
<i>Psychiatric symptoms</i>		
Depression	Tricyclic antidepressants	20–100 mg QD
	Mirtazapine	15–30 mg QHS
	Selective serotonin uptake inhibitors (SSRI)	20–100 mg QHS
	Venlafaxine	37.5–75 mg BID–TID
	Bupropion	100 mg TID
Anxiety	SSRI antidepressants	20–100 mg QHS
	Buspirone	10 mg TID
	Mirtazapine	15–30 mg QHS
	Benzodiazepines	0.5–5 mg BID–TID
	Trazadone	50–100 mg BID–TID
Psychosis/agitation	Neuroleptics (Haloperidol)	0.5–3 mg QD
	Atypical neuroleptics (Risperidone, Olanzapine, Quetiapine, Clozaril)	0.25–200 mg per day
	Benzodiazepines	0.5–30 mg per day
Irritability/aggression	SSRI medications	20–100 mg QD
	Divalproex sodium	250–2,000 mg per day
	Carbamazepine	100–2,600 mg per day
Pseudobulbar affect	SSRI antidepressants	20–100 mg QD
	Tricyclic antidepressants	20–100 mg QHS
Sialorrhea	Mirtazapine	15–30 mg QHS
	Venlafaxine	37.5–75 mg BID–TID
	Dextromethorphan/quinidine	30 mg/30 mg BID
	Lithium carbonate	300 mg QD–TID
	Tricyclic antidepressants	20–100 mg QHS
	Atropine sulfate	0.4 mg Q 4–6 h
	Glycopyrrolate	1–2 mg TID
<i>Motor symptoms</i>	Hycosamine sulfate	0.125–0.25 mg Q 4 h
	Diphenhydramine	25–50 mg TID
	Scopolamine transdermal patch	1.5 mg applied behind ear Q 72 h
	Scopolamine transdermal patch	1.5 mg applied behind ear Q 72 h
<i>Motor symptoms</i>		
Spasticity	Baclofen	10–60 mg TID
	Tizanidine	2–8 mg QID
	Dantrolene	25–100 mg TID
	Benzodiazepines	2–10 mg TID
	Quinine sulfate	260–325 mg QD
Cramps	Vitamin E	400 IU TID
	Phenytoin	300 mg QHS
	Diazepam	2–10 mg TID
Tremor	Dopaminergic medication	300–3,000 mg per day
	Amantadine	100–300 mg per day
	Beta blocker	10–30 mg BID–TID
	Primidone	50–250 mg QHS
	Clonazepam	0.5–2 mg QHS
Chorea	Neuroleptics	0.5–100 mg per day
	Atypical neuroleptics	0.5–160 mg per day
	Benzodiazepines	0.5–20 mg per day
	Amantadine	100–300 mg QD
<i>Autonomic symptoms</i>		
Orthostatic hypotension	Fludrocortisone	0.1–1 mg QD
	Midodrine	10 mg TID
<i>Gastrointestinal symptoms</i>		
Thick phlegm	Guaifenesin	200–400 Q 4 h
	Nebulized acetylcysteine	1 NEB Q 6–8 h
	Nebulized saline	1 NEB Q 4–6 h
	Beta blocker	10–30 mg TID
Constipation	Increase fluid intake	N/A
	Increase fiber intake	N/A
	Docusate sodium	100 mg QD–BID
	Milk of magnesia	N/A
	Dulcolax	5–15 mg QD
	Lactulose	15–30 mL QD–BID

(continued)

TABLE 39.3 (continued)

Symptom	Management	Dosage
<i>Gentourinary symptoms</i>	Magnesium citrate	120–240 mL PRN
	Polyethylene glycol	3,350 17 g QD
Urinary urgency	Oxybutynin	2.5–5 mg BID
	Tolterodine	1–2 mg BID
	Amitriptyline	25–75 mg QHS
	Oxytrol patch	3.9 mg QD
Erectile dysfunction	Sildenafil citrate	50 mg PRN
<i>Sleep disorders</i>		
REM sleep behavior disorder	Clonazepam	0.5–2 mg QHS
Insomnia	SSRI antidepressants	20–100 mg QD
	Tricyclic antidepressants	20–100 mg QHS
	Mirtazapine	15–30 mg QHS
	Zolpidem	5–10 mg QHS
	Eszopiclone	2–3 mg QHS
	Zaleplon	5–10 mg QHS
	Antihistamines	25–50 mg QHS
	Chloral hydrate	500–1,000 mg QHS
	Benzodiazepine	2–5 mg QHS

diseases, off label use, the prescription of an agent for a symptom or disease other than the one for which it is approved, is often helpful in improving quality of life for patients.

39.4.1. Psychiatric Symptoms

Many patients with neurodegenerative diseases exhibit psychiatric symptoms, including depression and anxiety. Tricyclic antidepressants, such as amitriptyline and nortriptyline, may relieve depression. However, the anticholinergic effects of these medications can lead to confusion and they must be used with caution in patients with cognitive compromise and in the elderly. Tricyclic antidepressants with low anticholinergic properties, such as desipramine or nortriptyline, can also be used. In PD, mirtazapine, which has noradrenergic and serotonergic effects, may relieve tremor in addition to reducing depression (Pact and Giduz, 1999; Gordon et al., 2002). While the selective serotonin reuptake inhibitor (SSRI) medications are helpful in the management of depression in all the disorders, they can exacerbate tremor, and sexual dysfunction is a common side effect.

Agitation, which may occur in patients with dementia, can be treated with anti-psychotics agents, mood stabilizing anti-convulsants, trazadone and anxiolytics (Doody et al., 2001). The atypical anti-psychotic medications are the treatment of choice for psychotic symptoms, such as hallucinations or delusions, particularly in those with Parkinsonism in whom dopamine receptor blockage is contraindicated due to the potential to worsen motor symptoms. In these patients, clozapine, which may reduce tremor in addition to its anti-psychotic effects, is particularly effective. However, rare cases of agranulocytosis necessitate weekly blood counts, and so limit its utility. Quetiapine may be the next agent of choice because it appears to have fewer adverse motor effects than the other medications

in the class (Ondo et al., 2005). Irritability and aggression can be seen in HD, and less commonly in PD with dementia, AD and ALS. SSRI medications and anticonvulsants such as valproic acid and carbamazepine can be effective in treating these symptoms.

In ALS, emotional lability or pseudobulbar affect can limit social interactions and quality of life. While there are no currently FDA approved therapies for pseudobulbar affect in ALS, SSRIs, tricyclic antidepressants and dopaminergic therapy can be beneficial (Gordon and Mitumoto, 2006). One randomized controlled trial showed that a combination of dextromethorphan and quinidine reduced emotional lability and improved quality of life in ALS (Brooks et al., 2004).

39.4.2. Sialorrhea

Drooling is an embarrassing symptom that is common in both ALS and PD. Anticholinergic medications are often helpful, but the benefits can be self limited and may require higher doses after initial improvement. Side effects include constipation, fatigue, and impotence. Urinary retention, blurred vision, tachycardia, orthostatic hypotension, dizziness and confusion may also occur. Drug selection depends on the severity and frequency of drooling. Hycosamine, which has a short half-life, is useful for sialorrhea that is associated with mealtimes or a particular time of the day. Transdermal scopolamine and oral glycopyrrolate provide a more continuous effect (Gordon and Mitumoto, 2006). Botulinum toxin injections have reduced sialorrhea in several small reports of both ALS and PD (Bushara, 1997; Pal et al., 1999; Bhatia et al., 1999), but need to be used with caution in those with dysphagia. Controlled trials are underway to determine the true benefit to risk ratio.

Thick phlegm can also be problematic in ALS. It is exacerbated by inadequate water intake, especially in patients

with bulbar weakness, and by use of anti-cholinergic agents, which reduce serous secretions while sparing mucous secretions. Pharmacologic treatments that loosen phlegm include guaifenesin, nebulized acetylcysteine, nebulized saline, or beta adrenergic receptor blockers such as propranolol (Gordon and Mitsumoto, 2006). Patients with a weak cough due to respiratory muscle involvement can use a cough-assist device or in-exsufflator to help clear secretions.

39.4.3. Motor Symptoms

In ALS, spasticity can be disabling. Baclofen, a gamma amino butyric acid analog, is the treatment of choice for spasticity, although the benefits are often modest. Patients may develop a sense of looseness or weakness, which can be minimized by slow dose titration. Other side effects include dizziness, fatigue and sedation. Intrathecal baclofen can be tried for those with severe or painful spasticity and inadequate response to oral treatment. Alternative medications to treat spasticity include dantrolene, tizanidine, and benzodiazepines. Dantrolene acts by blocking calcium release at the level of the sarcoplasmic reticulum and has the theoretical benefit of reducing excess neural excitation. At higher doses, liver function abnormalities may occur and require periodic monitoring. Tizanidine, an alpha 2 agonist that has proven benefit for spasticity in multiple sclerosis, has similar side effects to baclofen. Benzodiazepines can be effective for spasticity, painful spasm and cramps. However, these medications can produce sedation and respiratory depression in high doses (Gordon and Mitsumoto, 2006).

In PD, the most common motor symptoms are tremor, bradykinesia and rigidity. Beta blockers, primidone and clonazepam can be used to treat postural tremor. Muscle relaxants are occasionally used for painful rigidity. Most of the typical motor symptoms, including rest tremor, respond to disease-specific therapy, at least early in the disease course. Some levodopa-induced motor complications, including chorea, dystonia, myoclonus and akathisia (Fahn, 2000), can be reduced by prescribing lower more frequent doses of levodopa or by adding an anti-dyskinetic agent such as amantadine (Luquin et al., 1992).

Huntington disease can cause chorea, bradykinesia, rigidity, and postural instability, among other motor symptoms. The chorea is often most noticeable and usually responds to treatment with dopamine receptor blocking or dopamine depleting agents, but only at the expense of worsening bradykinesia. Atypical neuroleptics are also used to treat chorea and some behavioral symptoms. Other medications that are used to treat chorea include benzodiazepines and amantadine. Levodopa is not effective for bradykinesia due to HD because of its potential to worsen chorea and cognitive symptoms.

39.4.4. Autonomic Symptoms

Dysautonomia may produce orthostatic hypotension, sphincter abnormalities and sexual dysfunction. Orthostatic hypotension, particularly problematic in PD and Parkinson-plus syn-

dromes such as multiple system atrophy, can be treated with salt, fludrocortisone, and midodrine (Jankovic et al., 1993). Fludrocortisone is a corticosteroid, but the exact mechanism of its effect on blood pressure is not fully understood. Side effects are similar to other glucocorticoids and mineralcorticoids. Midodrine stimulates alpha-one adrenergic receptors. It can cause significant hypertension in the supine position. Other common side effects include paresthesias, piloerection, dysuria, and pruritis.

39.4.5. Gastrointestinal Symptoms

Constipation is a common symptom in the neurodegenerative disorders. Inadequate fluid intake, dysphagia, dysautonomia, and immobility all contribute to constipation. Increasing fluid and fiber intake, along with increasing physical activity can help. Use of docusate sodium, milk of magnesia, dulcolax and senna may also improve symptoms. For severe constipation, lactulose, magnesium citrate and enemas can provide relief.

39.4.6. Genitourinary Symptoms

In neurodegenerative disorders, patients often experience urinary urgency, which is thought to be caused by spasm of the urinary sphincter or detrusor muscle. Oxybutynin (Ditropan) and tolterodine (Detrol) are effective for urinary urgency. For ALS patients and some PD patients, swallowing tablets may be difficult due to dysphagia. Extended release oxybutynin allows for infrequent daily dosing and oxytrol patches avoids the oral route of administration.

Sildenafil citrate (Viagra) has been found to be safe and effective for managing erectile dysfunction in PD, but can unmask orthostatic hypotension in patients with multiple system atrophy (Zesiewicz et al., 2000; Hussain et al., 2001). Sildenafil is also effective for erectile dysfunction in other neurodegenerative disorders, but it should be used cautiously in those with cardiovascular disease.

39.4.7. Sleep Disorders

Sleeplessness in ALS has numerous causes. Respiratory insufficiency, difficulty repositioning in bed, anxiety and depression can all contribute to poor sleep. Treatment of depression with sedating antidepressants such as mirtazapine, tricyclic antidepressants, or trazadone can help promote sleep. Zolpidem, a non benzodiazepine sleep aid, is effective and carries a low risk of respiratory depression. Other medications that can be helpful include antihistamines, chloral hydrate and selective use of benzodiazepines (Gordon and Mitsumoto, 2006). Non-invasive positive pressure ventilation can help relieve orthopnea in those with respiratory muscle weakness, and special equipment, such as a hospital bed, can reduce nighttime discomfort.

The sleep dysfunction in PD may also be multifactorial, but can also be due to an underlying sleep disorder. Parkinson

disease is commonly associated with rapid eye movement (REM) sleep disorder (Comella et al., 1998), which can be an initial manifestation of the disease. REM sleep disorder, best diagnosed with an overnight sleep study, can be treated with a nighttime benzodiazepine such as clonazepam.

In AD, non-pharmacological approaches to treating insomnia are undertaken first. Techniques include sleep restriction and keeping patients awake during the day as well as providing a cool comfortable quiet sleep environment at night. If pharmacologic management is necessary, sedating antidepressants or zolpidem may be helpful for promoting sleep in AD (Corey-Bloom and Galaska, 1995). In those with nighttime confusion or sundowning, a low dose of a sedating atypical antipsychotic medication such as quetiapine can be helpful. Anticholinergic hypnotics should be avoided.

39.5. Current and Future Directions for Neuroprotection

39.5.1. Anti-Inflammatory Agents

39.5.1.1. Nonsteroidal Anti-Inflammatory Drugs (NSAIDs)

Because inflammatory cells surround dying neurons in all neurodegenerative disorders, a recent approach to neuroprotection has been the use of anti-inflammatory agents. Nonsteroidal anti-inflammatory drugs (NSAIDs) reduce inflammation in part by inhibiting one or both of the cyclooxygenase (COX) enzyme isoforms. Inhibition of COX reduces prostaglandin synthesis leading to a general decrease in inflammation. While NSAIDs have demonstrated an ability to provide neuroprotection in animal models, human trials have been less rewarding.

Both celecoxib and rofecoxib, selective COX-2 inhibitors, had positive effects in the SOD1 mouse model of ALS (Drachman et al., 2002; Azari et al., 2005). A subsequent randomized controlled trial of celecoxib was negative, however. A statement released by the investigators in 2004 reported that celecoxib did not impart a beneficial effect in 300 ALS patients. There were no differences in adverse effects between treated and control groups and the drug was well tolerated at a dosage of 800 mg/day (www.alsa.org). This trial had a high dropout rate, which may have impaired the ability of the investigators to detect a small impact of the drug if one existed.

Celecoxib and rofecoxib have also been studied in AD. Randomized double blind, placebo controlled trials failed to demonstrate a therapeutic benefit (Sainetti et al., 2000; Aisen et al., 2003). The rofecoxib trial used naproxen as a control; the results were consistent with other studies in which nonselective NSAIDs such as diclofenac, have been ineffective in AD (Scharf et al., 1999). Other NSAIDs including ibuprofen, indomethacin and sulindac sulfide have demonstrated potential efficacy in AD (Rogers et al., 1993; t'Veld et al., 2001), but definitive trials have not yet been conducted.

39.5.2. Immunomodulation

39.5.2.1. Vaccination in ALS

Another approach is to harness the body's own immune system to regulate inflammation. In models of neurodegeneration caused by mechanical or biochemical injury, more neurons survive in the presence of a well-regulated evoked anti-self T cell mediated response (Moalem et al., 1999). Vaccination can be used to induce nonpathogenic T-cell responses, including the activation of anti-inflammatory Th2 cells, which may migrate to lesion sites where they affect innate immune responses through the release of anti-inflammatory cytokines or by inducing the production of neurotrophic factors. Glatiramer acetate (Copaxone, Cop-1), a mix of amino acids in a known molar ratio, was originally designed to mimic myelin basic protein and is now FDA approved for the treatment of multiple sclerosis (MS). Cop-1 can induce a protective T cell mediated response without risk of causing an autoimmune disease. A study of acute and chronic motor neuron disease in animal models demonstrated that twice the number of motor neurons survived in Cop-1 vaccinated mice than control mice (Angelov et al., 2003). This study also showed that Cop-1 vaccination prolonged life span in SOD1 transgenic mice, although pathological findings were not reported. An initial trial in ALS patients revealed the modality to be safe in this disease (Gordon et al., 2006). ALS patients tolerated two different dosing frequencies in conjunction with riluzole, and patients mounted immune responses similar to those seen in MS patients. Larger trials of efficacy are planned.

39.5.2.2. Immunization in AD

In AD, locally generated complement proteins are activated by extracellular amyloid deposits. Microglia aggregate at the site, attacking and destroying neuronal extensions. Research has focused on recruiting the immune system to remove beta amyloid protein deposits. Exogenous antibodies to beta amyloid protein selectively bind to senile plaques and cerebral amyloid *in vivo*, and the amyloid deposition can be ameliorated in beta amyloid precursor protein-transgenic mice by active immunization with the beta amyloid peptide (Walker et al., 1994). Other studies have confirmed that diverse anti-beta amyloid immunization schemes reduce cerebral beta amyloid burden and behavior deficits in AD transgenic mice (Dodel et al., 2003; Lemere et al., 2004).

Beta amyloid immunization was initiated in humans after the successful studies in rodents. Phase I studies were completed without major adverse events and Phase II trials were initiated with AN 1792 (active immunization with amyloid beta 42 and QS-21 adjuvant). The trials were interrupted in 2002 because approximately 6% of those vaccinated developed aseptic meningitis (Orgogozo et al., 2003). Data from the incomplete trial suggest that AD patients who mounted a significant antibody response also showed signs of clinical benefit (Orgogozo et al., 2003; Hock et al., 2003). Autopsy findings from three patients who died approximately 1 year

after the first immunization showed evidence of beta amyloid clearance (Nicoll et al., 2003; Ferrer et al., 2004; Masliah et al., 2005). However, two of the three brains also showed changes of encephalitis with infiltration of T lymphocytes, white matter lesions invaded by macrophages, and in one case, severe small vessel disease with multiple cortical hemorrhages (Nicoll et al., 2003; Ferrer et al., 2004). The potential for beta amyloid immunization to be developed further as a disease modifying treatment in AD depends on whether the serious side effects can be effectively controlled. Further studies are needed, especially in aged nonhuman primates, to clearly understand the adverse effects and how to allow for safe application of this therapy to humans (Orgogozo et al., 2003).

39.5.2.3. Immunotherapy in Prion Disease

Antibody based immunotherapy has also been evaluated in the animal models of prion disease. *In vitro* assays have demonstrated that antibodies to the cellular prion protein (PrP_C) antagonize the deposition of disease associated prion protein (PrP_{Sc}) (Sigurdsson et al., 2002). However, the induction of protective antiprion immune responses has been difficult in wild type animals because of tolerance to endogenous PrP_C. Some studies have shown that it might be possible to overcome this tolerance by inducing immune responses to bacterially expressed recombinant PrP (Heppner et al., 2001). However, developing antibodies that are capable of recognizing native cell surface PrP_C is more difficult (Heppner and Aguzzi, 2004). One study demonstrated that anti-PrP antibodies cross-linked with PrP_C when directly injected into the brains of laboratory animals and subsequently provoked neurotoxicity (Solfors et al., 2004). However, passive immunization and antibody transgenesis experiments have been successful in animals (White et al., 2003). Further studies are required to determine the mechanism of tolerance needed to safely and successfully implement vaccination as an antiprion regimen.

39.5.2.4. Immunotherapy in Parkinson's Disease

In the MPTP animal model of PD, glatiramer acetate (Cop-1) has also been investigated. In the MPTP model, Cop-1-immune cells provided significantly more neuroprotection than placebo (Benner et al., 2004). Mice received adoptive transfers of splenocytes from Cop-1 or ovalbumin immunized mice because MPTP-immunotoxicity precluded active immunization due to lymphotoxicity (Benner et al., 2004). In animals given splenocytes from Cop-1 immunized mice, T cells entered and accumulated in inflamed areas of the CNS. The T cells secreted interleukin-10, an inhibitory Th2 cytokine, which suppressed microglial activation, and also stimulated local expression of astrocyte-associated glial cell line derived neurotrophic factor. This immunization strategy minimized dopamine loss compared to control animals and resulted in significant protection of nigrostriatal neurons. Human trials are planned in PD, but investigations are needed to define the best routes of administration and dosing frequencies.

Immunophilin binding proteins are being developed as a potential immune based therapy in PD. Immunophilins, intracellular receptor proteins that bind to the immunosuppressive drugs cyclosporine A, FK506, and rapamycin, are 10–50-fold more abundant in the brain than in the immune system (Guo et al., 2001). The immunophilin ligands combine with immunophilin proteins to suppress the immune system by inhibiting the calcium activated phosphate calcineurin, and some promote nerve growth *in vitro* and *in vivo*. GPI 1046 (Guilford Pharmaceutical) and AMG-474-00 or NIL-A (Amgen) are immunophilin ligands that promote neuronal growth without demonstrating immunosuppressive effects (Steiner et al., 1997; Gold et al., 1998). These agents stimulate growth of nigrostriatal dopaminergic neurons spared after MPTP-induced damage to the substantia nigra. Human trials are planned to determine whether these or other immunophilin ligands will be useful in slowing or reversing PD.

39.5.3. Anti-apoptotic Therapies

Neurodegeneration is likely due in part to caspase enzyme driven apoptosis and drugs that inhibit the activation of caspase enzymes are being studied as a potential neuroprotective strategy.

39.5.3.1. Minocycline

Minocycline is a tetracycline antibiotic with anti-inflammatory and anti-apoptotic properties. It has been shown to delay disease onset and prolong survival in transgenic ALS mice (Zhu et al., 2002; Kriz et al., 2002). Two early phase randomized controlled trials indicated that minocycline could be used safely in high doses and in conjunction with riluzole (Gordon et al., 2004). but minocycline caused a worsening of function in a recent phase III trial (Gordon et al., 2007). A separate efficacy trial is just underway in Europe, so that cumulative data may determine the true effect of minocycline in ALS.

Markers of apoptosis are also present in PD (Mogi et al., 2000; Tatton, 2000). Injection of minocycline into the 6-OHDA mouse model of parkinsonism inhibits microglial activation, protects dopaminergic neurons, and reduces markers of apoptosis (He et al., 2001). Minocycline has also been shown to prevent nigrostriatal dopaminergic neurodegeneration in MPTP mice models of PD (Du et al., 2001). Similarly, minocycline delays disease progression in animal models of HD, presumably by inhibiting caspase-1 and caspase-3 mRNA up regulation and decreasing inducible nitric oxide synthase (iNOS) activity (Chen et al., 2000; Tikka et al., 2001). Phase II NINDS-funded clinical trials testing minocycline in PD are underway. The unfortunate untoward effects of a well-known anti-inflammatory agent minocycline, an antibiotic in the tetracycline family, in a randomized phase III clinical trial (Gordon et al., 2007) is cause for pause. Minocycline treatment of ALS patients not only demonstrated no beneficial effect, for some patients it significantly worsened measurable neurologic outcomes. Those who were taking the drug to ALS

were asked to discontinue its use. Regrettably, the drug did not affect survival or quality of life measures for people with ALS and raised caution in extrapolating animal model data for human use (Lancet Neurol. 2007 Dec;6(12):1045–53).

39.5.3.2. TCH 346 (*Omigapil*)

TCH 346, which is structurally related to selegiline, binds to glyceraldehyde 3 phosphate dehydrogenase (GAPDH) in a mechanism that may prevent programmed cell death. It slows the degeneration of motor neurons in *in vitro* models of apoptosis (Carlile et al., 2000), but did not have significant effect on survival in transgenic mice. Phase IIa and IIb trials in ALS showed that the drug did not slow the rate of progression or prolong survival at any of the doses tested (www.als.net/treatments/clintrials/clinics_detailed.asp).

In PD, a nuclear translocation of GAPDH in melanized nigral neurons has been interpreted as a marker for apoptosis (Dastoor and Dreyer, 2001). After MPTP treatment in animal models, GAPDH is up regulated and undergoes nuclear translocation. TCH 346 has been shown to bind to GAPDH and rescue neurons from cell death in this model (Andringa and Cools, 2000). TCH346 also attenuates MPTP-induced toxicity in primates (Andringa et al., 2003). However, further studies are needed to determine whether GAPDH upregulation and nuclear translocation, and whether the effects of TCH346 are meaningful changes in PD. Clinical trials have been initiated.

39.5.3.3. Mitogen Activated Protein (MAP) Kinase Inhibitors

The cascade of apoptosis may be promoted by mitogen activated protein (MAP) kinase activation. CEP1347, a small molecule MAP kinase inhibitor that crosses the blood brain barrier is protective in MPTP-treated mice (Saporito et al., 1999). A clinical trial showed good tolerability, no interference with L-dopa pharmacokinetics, and no symptomatic effects of treatment over a 4-week period (Parkinson Study Group, 2004). A larger phase II trial has commenced.

39.5.4. Antioxidants

Another proposed mechanism of neuronal death is oxidative stress due to the accumulation of free radicals. Normal and abnormal cellular metabolic processes involving molecular oxygen produce free radicals, which can cause oxidative damage to lipids, proteins and nucleic acids (Andersen, 2004).

39.5.4.1. Vitamin E

Alpha tocopherol (vitamin E), a naturally occurring antioxidant, delays disease onset in SOD1 transgenic mice (Gurney et al., 1996). One epidemiological study suggested that regular intake of vitamin E may reduce the risk of contracting ALS (Ascherio et al., 2005). A randomized, placebo controlled trial of vitamin E 500 mg twice daily showed

no significant difference in 12-month survival in patients with ALS (Desnuelle et al., 2001). This trial was probably underpowered due to insufficient sample size, and used an unvalidated outcome measure, the Norris Scale. Vitamin E has also been studied in combination with other antioxidants. L-methionine, vitamin E, and selenium were studied in ALS in a double blind placebo controlled trial of the combinations taken three times a day (Stevic et al., 2001). After 12 months there was 50% survival in the control group and 81% in the treatment group, findings that were not statistically significant (Orrell et al., 2005). Vitamin E was ineffective in slowing progression of PD in the DATATOP trial (Parkinson Study Group, 1989).

39.5.4.2. Selegiline

Selegiline may have anti-oxidant and anti-apoptotic properties in addition to inhibiting MAO, and has been reported to increase SOD activity in the basal ganglia of rats (Knoll, 1989). There have been several trials of selegiline 10 mg per day in patients with ALS: a randomized, placebo controlled, double blind trial (Lange et al., 1998), and a placebo-controlled crossover trial (Mitchell et al., 1995). Neither showed improvement in functional or subjective rating scales, but both trials were underpowered due to insufficient sample size and so may be considered inconclusive.

39.5.4.3. N-acetylcysteine

N-acetylcysteine, a precursor of glutathione, which is a natural intracellular antioxidant, has been tested in a randomized, placebo controlled trial in patients with ALS. Thirty-five patients (65%) given N-acetylcysteine 50mg/kg subcutaneous infusion daily and 30 patients (54%) given placebo were still alive at 12 months, a difference that was not statistically significant (Louwerse et al., 1995).

39.5.4.4. Coenzyme Q10 (*CoQ10*)

CoQ10 is an essential cofactor of the mitochondrial electron transport chain, and may act as an antioxidant. It has been shown to have neuroprotective effects in models of ALS, PD and HD (Beal, 2002). An open label escalation trial in ALS was completed in 2004; dosages up to 3,000 mg per day were well tolerated (Ferrante et al., 2005). An NINDS-funded randomized controlled phase II trial of CoQ10 is currently underway in patients with ALS.

A phase II trial has also been completed in PD (Shults et al., 2002). Over a period of 16 months, CoQ10 was safe and well tolerated at doses up to 1,200 mg/day. Trends toward less disability occurred in treated patients and the benefits were greater in those receiving the highest dosage. However, larger studies, including an examination of the potential symptomatic effects of CoQ10, over a longer period of time are needed to determine the efficacy of CoQ10 as a neuroprotective agent in PD.

39.5.4.5. AEOL 10150

AEOL 10150 (manganese (III) meso-tetrakis (di-N-ethyl-imidazole) porphyrin) is a compound that can catalytically decompose biological oxidants such as peroxynitrite via its ability to cycle between MN (III) and MN (IV) states. Several investigators have reported the presence of nitrotyrosine in affected tissue in motor neuron disease; however, no cause and effect relation between protein nitration and neuronal death has been established (Crow et al., 2005). AEOL 10150 prolonged survival in the SOD1 ALS model. A phase I dose ranging clinical trial reported a high degree of safety in this population. Multi-dose studies are underway.

39.5.5. Trophic Factors

39.5.5.1. Insulin-Like Growth Factor

Nerve growth factors promote neuronal sprouting *in vitro*, and reduce nerve cell death *in vivo*. Viral delivery of insulin like growth factor (IGF-1) was shown to prolong survival and delay the onset of disease in the ALS mouse model (Kaspar et al., 2003). Two randomized controlled trials of IGF-1 have been completed in ALS. One showed slowed progression of functional impairment using an unvalidated outcome measure (Lai et al., 1997). The second trial showed no significant change using the same outcome (Borasio et al., 1998). A third trial, using strength testing as the primary outcome, has just completed enrollment. Human trials of viral vector delivery are planned but the safety of the modality must be shown before the FDA will allow trials to proceed.

In PD, animal studies are underway with IGF-1. N-terminal tripeptide of IGF-1 was peripherally administered to 6-OHDA mouse models of PD and results indicated that administration after the onset of nigrostriatal dopamine depletion improved long term parkinsonian motor deficits; however IGF-1 administration did not prevent the loss of tyrosine hydroxylase in the substantia nigra pars compacta or the striatum (Krishnamurthi et al., 2004). Human trials of IGF have not yet been conducted in PD.

39.5.5.2. Vascular Endothelial Growth Factor

Vascular endothelial growth factor (VEGF) is needed for angiogenesis and has been implicated in neurodegeneration (Jin et al., 2000). Researchers have shown that low levels of VEGF in transgenic mice can cause an ALS-like syndrome. Intramuscular delivery of VEGF delays onset and prolongs survival in SOD1 mice (Storkebaum et al., 2005).

VEGF has also been shown to promote neuroprotection in the 6-OHDA mouse model of PD by activating the proliferation of glia and by promoting angiogenesis (Yasuhara et al., 2004). Human trials will likely be initiated in the future, once optimal dosing and route of administration have been established.

39.5.5.3. Brain Derived Growth Factor

Brain derived neurotrophic factor (BDNF) has been shown to prolong survival, protect against glutamate neurotoxicity, and slow disease progression in the wobbler mouse, an early model of ALS. Unfortunately, BDNF did not show benefit in patients with ALS (Anonymous, 1999).

BDNF was also evaluated in the rat model of PD, and was compared to glial cell line derived neurotrophic factor (GDNF); results of the study showed that GDNF was more effective than BDNF in the model, but that there were no significant benefits from either of these neurotrophic factors (Sun et al., 2005).

39.5.5.4. Ciliary Neurotrophic Factor

Ciliary neurotrophic factor (CNTF) was also shown to protect wobbler mice, to be required for preservation of adult motor neurons in knockout mice, and to reduce immunoreactivity in the spinal cord of ALS patients. This drug advanced as far as Phase III clinical trials, however, no significant difference in survival was observed between CNTF and placebo groups (ALS CNTF Treatment Study Group, 1996; Hurko and Walsh, 2000).

CNTF has also been investigated in mouse models of PD. Although CNTF had potent neurotrophic effects for injured adult rat dopaminergic substantia nigra neurons, it did not prevent the disappearance of the transmitter synthesizing enzyme tyrosine hydroxylase (Hagg and Varon, 1993). Human trials were not conducted.

39.5.5.5. Glial Derived Neurotrophic Factor

Glial Derived Neurotrophic Factor (GDNF) has been a particularly promising approach to neuroprotection in ALS and PD (Lapchak, 1998; Gash et al., 1998). GDNF enhances survival of the midbrain dopaminergic neurons *in vitro* and rescues degenerating neurons *in vivo* (Tseng et al., 1997). Intraventricular administration of GDNF in monkeys ameliorated parkinsonism and produced 20% enlargement of nigral neurons accompanied by increased fiber density (Gash et al., 1996). A GDNF-levodopa combination reportedly reduced levodopa side effects in experimental monkeys (Miyoshi et al., 1997). A pilot trial in humans with moderately advanced PD was abandoned, however, because of lack of efficacy and the frequent occurrence of nausea, anorexia, tingling, hallucinations and depression (Nutt et al., 2003). Autopsy of one case showed no evidence of significant trophic effects on nigrostriatal neurons (Kordower et al., 1999). Trials in ALS were similarly abandoned due to high levels of toxicity.

Laboratory studies are now using a lentoviral vector to deliver GDNF to the striatum of monkeys with MPTP-induced Parkinsonism. One study demonstrated reversal of functional deficits, extensive and long term GDNF expression, augmentation of dopaminergic function, and prevention of nigrostriatal degeneration (Kordower et al., 2000). This new delivery system provides a hopeful therapeutic strategy for PD, and has also been beneficial in the SOD1 model of ALS.

39.5.6. Antiglutamatergic Agents

39.5.6.1. Gabapentin

Gabapentin, an antiepileptic agent, may reduce glutamate release and thereby, reduce excitotoxicity. Gabapentin showed a small but significant effect on survival in SOD1 transgenic mice (Gurney et al., 1996). An early phase clinical trial in ALS showed a non-significant slower rate of decline in arm strength due to gabapentin (Miller et al., 1996). A phase III study using a higher dose revealed no change in strength and a more rapid rate of decline of the forced vital capacity (Miller et al., 2001), exemplifying the need to better define dose in early phase trials before proceeding to definitive trials.

39.5.6.2. Topiramate

Topiramate reduces glutamate release from neurons and antagonizes activation of the alpha-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) receptor, a glutamatergic excitatory amino acid receptor. A double-blind, placebo-controlled trial conducted in 296 ALS patients over 12 months showed a faster rate of decline in arm strength and no effect on survival from topiramate (Cudkowicz et al., 2003). This trial had a large dropout rate and proceeded to a phase III trial without first exploring the effects of topiramate in the SOD model.

Topiramate was recently studied in the marmoset model of PD (Silverdale et al., 2005). Overactive AMPA receptor-mediated transmission may be involved in the pathogenesis of levodopa-induced dyskinesias. Topiramate significantly reduced levodopa-induced dyskinesias without affecting the antiparkinsonian action of levodopa. Further studies are needed to better elucidate the potential benefits of topiramate in PD.

39.5.6.3. Lamotrigine

Lamotrigine is another glutamate release inhibitor that has been studied in neurodegenerative diseases. In ALS, 300 mg of lamotrigine per day had no effect when compared to placebo in a small number of patients (Ryberg et al., 2003). Lamotrigine also failed to show symptomatic benefit in patients with PD (Shinotoh et al., 1997), but neither study had adequate power to truly assess efficacy.

39.5.6.4. Ceftriaxone

Ceftriaxone was selected from the recent NIH-supported high throughput screening initiative in ALS. Approximately 1,050 FDA approved drugs, for which the safety and toxicity are already known, were screened using *in vitro* assay systems (cell survival, cytochrome C release, protein aggregates, etc.). Positive results or "hits" were then tested in the transgenic model. Ceftriaxone was shown to increase glutamate transporter activity and prolong motor neuron survival. Ceftriaxone is a third generation cephalosporin that also protects against SOD toxicity, radiation induced neurodegeneration in

in vitro models (Tikka et al., 2001), and has the ability to cross the blood brain barrier. Clinical trials funded by the NINDS are expected to begin in 2006, with the goal of determining the pharmacokinetics, safety and efficacy of long-term ceftriaxone treatment in ALS.

39.5.6.5. Talampanel

Talampanel, an AMPA antagonist with antiglutamatergic activity, is also being evaluated in neurodegeneration. Talampanel has been shown to be neuroprotective after traumatic brain injury in rats (Belayev et al., 2001), and AMPA receptor antagonists have been shown to prolong survival in the transgenic mouse model of ALS (Van Damme et al., 2005). Phase II trials of talampanel are underway in both PD and ALS.

39.5.6.6. Remacemide

Remacemide, an anticonvulsant and NMDA antagonist, is being studied in PD. It has been shown to enhance the effects of levodopa in rats and monkeys (Greenamyre et al., 1994). A randomized, controlled trial of remacemide in 279 patients with PD and motor fluctuations showed trends towards improvement of "on" time, but no evidence of neuroprotection (Parkinson Study Group, 2001). In a small HD trial, remacemide tended to alleviate chorea but failed to slow functional decline (Huntington Study Group, 2001).

39.5.7. Stem Cell Transplant Therapy

Advances in stem cell therapy have received a great deal of press in recent years. Unfortunately, when public expectations have been raised, patients are likely to search for non-orthodox sources of treatment. There are tens of thousands of internet pages extolling the promise of stem cells, and various forms of stem cell therapy are available on a commercial basis in a number of countries, including China, South America, and Eastern Europe. However, most administer the stem cells in an uncontrolled way and do not have long term follow-up so that rational scientific conclusions cannot be reached. The science provides hope for potential therapeutic interventions in neurodegenerative diseases, but it is in its early stages and much is still needed to be learned about how to control stem cell proliferation, differentiation into specific cells and optimal functional recovery in animal models before human trials. The collection and use of human fetal tissue may also raise ethical concerns.

39.5.7.1. Stem Cell Therapy and Parkinson's Disease

The loss of specific dopaminergic neurons in PD makes the prospect of replacing missing or damaged cells a potential therapy. Recent double blind placebo controlled trials of primary human embryonic dopaminergic tissue used functional neuroimaging and neuropathological investigations to demonstrate integration of transplanted dopaminergic neurons in host striatum (Freed et al., 2001; Olanow et al., 2003). However, only subpopulations of PD patients displayed significant

benefits, and some patients developed uncontrollable side effects due to excess dopamine production.

Retinal pigmented epithelia (RPE) are dopaminergic support cells in the neural retina. RPE cells on gelatin beads, also called Spheramine, produce levodopa (Watts et al., 2003), but there are no data yet on the consistency of dopamine production by these cells. An open label clinical trial of transplantation of Spheramine was conducted in six patients with PD (Bakay et al., 2004). Spheramine was transplanted into the striatum and showed clinical effects over 24 months. Spheramine is now undergoing double blind placebo controlled trials in advanced PD.

39.5.7.2. *Stem Cell Therapy and Huntington's Disease*

In animal models of HD, transplanted striatal cells have survived, grown and established afferent and efferent connections (Freeman et al., 2000). One open label human trial indicated that grafts may have restored function (Hauser et al., 2002). Recipients showed cognitive and motor improvements that were associated with reductions in striatal and cortical hypometabolism. The success of grafting may be sensitive to the age of the donor and to the degree of neuronal loss in the patient. Clinical trials are in early phases and there still needs to be resolution of a number of technical issues (Gardian and Vecsei, 2004).

39.5.7.3. *Stem Cell Therapy and Amyotrophic Lateral Sclerosis*

Stem cell therapy poses a greater challenge in ALS than in other neurodegenerative diseases because of the length of motor axons and growing evidence that neurodegeneration in ALS may be mediated by neuronal and glial influences. Late stage fetal cortical neurons have been shown to replace apoptotic neurons when grafted into adult mouse neocortex, to receive afferents from host brain, and to project to the contralateral hemisphere (Fricker-Gates et al., 2002). Fetal motor neurons grafted to the adult rat spinal cord lacking motor neurons migrate to the ventral horn and make functional connections with skeletal muscle (Clowry et al., 1991). Whether these neurons are integrated into neuronal circuits is unclear. It is also unknown if similar neuronal replacement could work in the brains of individuals with ALS. Clinical trials have shown the general safety of cerebrospinal fluid injection in small numbers of patients, but there was no means to monitor cell growth, or even to determine if the cells survived (Mazzini et al., 2003). There is still a great deal of research to be done with stem cell therapy before it can be effectively implemented in ALS.

39.5.8. Others

39.5.8.1. *Amyotrophic Lateral Sclerosis*

39.5.8.1.1. Calcium Channel Blockers

Calcium channel blockers antagonize excitatory amino acid receptor activation. A randomized, double blind, placebo controlled, crossover study of nimodipine was conducted in

patients with ALS (Miller et al., 1996b). There was no significant difference in the rate of decline of pulmonary function or limb strength with treatment compared to placebo and the authors concluded that nimodipine was ineffective in slowing the progress of ALS.

The efficacy of verapamil, a calcium channel blocker, was studied in a clinical trial in which the treatment of phase was compared to a natural history phase (Miller et al., 1996c). During months 1 to 3, patients were not given drug and the natural history of their progression was measured. Following the month 3 visit, verapamil was started at 40 mg and titrated to a daily dose of 240 mg per day. The decline in forced vital capacity and limb strength were not significantly different between the treatment phase and natural history phase.

39.5.8.1.2. Creatine

A key pathological feature in the animal model of ALS is abnormality of the mitochondria (Wong et al., 1995). Creatine, which acts as a mitochondrial energy buffer and may also have anti-oxidant properties, provided a dose dependent improvement in survival in the transgenic SOD1-G93A mouse (Klivenyi et al., 1999). A subsequent randomized placebo-controlled trial using 5 g per day showed no significant benefit in survival (Groeneweld et al., 2003). This trial broke new ground in several ways. First, the investigators used a sequential analysis plan, so that the trial was stopped once the null hypothesis could no longer be rejected, saving 18 months over a fixed duration trial. Second, the dropout rate was nearly zero, because the investigators made home visits when necessary to obtain data from patients no longer able to travel to the centers. A second double blind placebo controlled trial of 5 g per days also did not show a benefit (Shefner et al., 2004), but this trial likely had inadequate power due to small numbers of patients enrolled. Neither trial may have been dosed adequately.

39.5.8.1.3. Sodium Phenylbutyrate

Transcriptional dysregulation may contribute to the pathogenesis of neurodegeneration (Gonzalez de Aguilar et al., 2000). Sodium phenylbutyrate, a histone deacetylase inhibitor (HDAC inhibitor), regulates transcription and has provided improvement in survival, body weight and motor performance in the SOD mouse model (Ryu et al., 2005). The safety and tolerability of sodium phenylbutyrate is currently being evaluated in a trial funded by the Veterans Administration and the Muscular Dystrophy Association.

39.5.8.1.4. Arimocloamol

Motor neurons may have a high threshold to activation of the heat shock protein pathway, which is involved in protein repair. Arimocloamol, an inducer of heat shock proteins, delays disease progression and improves survival in the murine model (Kieran et al., 2004). Early phase trials with arimocloamol in patients with ALS are currently underway.

39.5.8.1.5. Ribonucleic Acid Interference

Mutant gene expression leading to neurodegeneration might be reduced by gene silencing techniques. RNA interference (RNAi) molecules have been generated that targeted the SOD1 gene and reduce its expression. RNAi has prolonged survival in the SOD1 model (Ralph et al., 2005; Raoul et al., 2005). The technology will only apply to the 2–5% of patients whose ALS is due to mutations in the gene encoding SOD1, and so obtaining adequate numbers of patients to conduct clinical trials may be difficult.

39.5.8.1.6. Combination Therapy

Because of the complexity of the mechanisms underlying neurodegeneration, testing combinations of agents that target different processes could theoretically be more beneficial than individual agents alone. The combinations of minocycline and creatine, and celecoxib and creatine showed additive effects in the SOD1 model (Zhang et al., 2003; Klivenyi et al., 2004). Phase II clinical trials using a novel selection trial design to identify the better performing combination have begun (Gordon et al., 2005).

39.5.8.2. *Alzheimer's Disease*

39.5.8.2.1. Statins

Statins, used predominantly in the treatment of hypercholesterolemia, act by inhibiting 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase, which regulates the synthesis of cholesterol. Statins are also agonists of peroxisome proliferator activated receptors (PPARs), which are part of the nuclear receptor superfamily and when activated, can suppress transcription of pro-inflammatory genes (Chinetti et al., 2000). *In vitro* and *in vivo* studies have shown that a decrease in serum cholesterol inhibits the production of beta amyloid and plaque (Simons et al., 1998; Fassbender et al., 2001). A randomized, controlled trial evaluating the efficacy of simvastatin on disease progression in patients with AD provided conflicting results. Overall, the plasma levels of beta amyloid protein remained relatively unchanged after 6 months of treatment, but those with better cognitive function demonstrated a greater reduction in beta amyloid protein levels than patients with more severe dementia (Simons et al., 2002). The mechanism of how lowering cholesterol affects beta amyloid production is still unclear; studies have demonstrated that statins do not alter beta amyloid morphology (Hoglund et al., 2004). It may be that the neuroprotective properties of statins are due to antioxidant and anti-inflammatory effects.

39.5.8.2.2. Secretase Inhibitors

Beta amyloid peptide is cleaved from the beta amyloid precursor protein by the beta secretase (or beta amyloid cleaving enzyme, BACE) and gamma secretase enzymes (Cummings, 2004). Experimental studies in animal models

have shown that secretase inhibition lowers the amount of beta amyloid protein in the brain and can reduce the formation of beta amyloid protein aggregates (Dewachter and Van Leuven, 2002). While BACE and gamma secretase are viable therapeutic targets, they have thus far been refractory to drug development. Gamma secretase inhibitors diminish beta amyloid protein load in the brain, but also cleave other proteins essential for signaling in cellular proliferation. Gamma secretase is essential for embryogenesis and gamma secretase knockout mice are not viable (Dewachter and Van Leuven, 2002). Until these limitations can be overcome, the potential for gamma secretase inhibitors for AD therapy is restricted.

BACE is another therapeutic target. One study showed that raising BACE expression increased plaque load in beta amyloid precursor protein-transgenic mice (Willem et al., 2004). However, the development of pharmacological inhibitors of BACE has been challenging due to its large catalytic site, which does not bind small molecules effectively.

39.5.8.3. *Huntington's Disease*

39.5.8.3.1. Sodium Phenylbutyrate

Impaired gene transcription is thought to be a key event in the cascade that leads to neurodegeneration in HD. Mutant huntingtin can bind to histone acetyltransferase, reducing histone acetylation and ultimately suppressing gene transcription. HDAC inhibitors act to relax the DNA conformation and facilitate transcription by keeping DNA acetylated. HDAC inhibitors may also be effective in preventing sequestration of certain transcription factors by mutant huntingtin during the process of aggregation (Ferrante et al., 2003). Sodium phenylbutyrate was tested in the R6/2 mouse model of HD and was shown to significantly increase survival, improve motor function and minimize brain atrophy (Gardian et al., 2005). Sodium phenylbutyrate is currently being tested in human trials.

39.5.8.3.2. Ethyl-EPA

Ethyl-EPA (ethyl-eicopentaenoate) is a semisynthetic, highly purified derivative of the n-3-fatty acid EPA. Ethyl-EPA acts to preserve mitochondrial function by targeting peroxisome proliferator activated receptors. Ethyl-EPA reduces loss of neuronal function by inhibiting caspase activation and apoptosis, and by reducing mitochondrial damage in models of neurodegeneration (Van Raamsdonk et al., 2005). A randomized double blind placebo controlled trial of ethyl-EPA was conducted in patients with HD. This study showed that there was no benefit in the intent to treat cohort of patients with HD. However, exploratory analysis revealed that a significantly higher number of patients in the cohort treated with ethyl-EPA showed stable or improved motor function (Puri et al., 2005). Further studies of ethyl-EPA efficacy are warranted.

39.5.8.4. *Parkinson's Disease*

39.5.8.4.1. Creatine

Administration of MPTP produces parkinsonism in experimental animals by a mechanism involving impaired energy production. MPTP is converted to 1-methyl-4-phenylpyridinium (MPP⁺), which blocks complex I of the electron transport chain. Supplementation with creatine, a substrate for creatine kinase, may increase phosphocreatine and cyclophosphocreatine levels, buffer against ATP depletion and exert neuroprotective effects. Oral supplementation of creatine produced significant protection against MPTP-induced dopamine depletion in mice (Matthews et al., 1999). Based on these results, a randomized, double-blind, futility clinical trial of creatine was recently conducted (NINDS NET-PD Investigators, 2006). The study found that creatine and separately, minocycline, could not be rejected as futile and that they should be considered for Phase III clinical trials to determine whether they alter the long-term progression of Parkinson disease.

Summary

Until the 1990s, progress in developing therapy for neurodegenerative diseases was slow and there were few clinical trials. However, with the advent of animal models and the recent advances in understanding the basic pathophysiological mechanisms underlying the diseases, potential therapies to prevent, delay the onset or slow the progression of neurodegenerative disease are being identified at an ever increasing rate. High throughput technologies are being used to screen large numbers of potential therapeutic agents and new developments in the realms of immune modulation, RNA interference, viral vector delivery of gene products and stem cell therapy hold great promise for the future. There are still many unanswered questions regarding the mechanisms of disease and why beneficial therapy in animal models has not translated well into human clinical trials. Neurodegenerative diseases are rare, and so identifying enough patients to obtain studies with adequate power has been difficult. Novel phase II designs are now being used to screen greater numbers of agents and to better define correct dosing before proceeding to phase III trials. Multicenter phase III trials are being designed with adequate power, and using meaningful validated outcome measures that reduce the high dropout rates of past trials. Agents are now being tested in combination in order to detect possible additive effects. Focus is also being given to the need to better define the best symptomatic therapies in randomized controlled trials. Further research will prompt more targeted therapies that we hope will soon provide truly meaningful breakthroughs for neurodegenerative disorders.

Review Questions/Problems

- Which one of these medications for Alzheimer's disease is NOT a cholinesterase inhibitor?**
 - galantamine
 - rivastigmine
 - tacrine
 - memantine
- What are the side effects that limit the prolonged usefulness of levodopa therapy in Parkinson disease?**
 - muscle fasciculation
 - motor fluctuations and dyskinesias
 - postural instability
 - bradykinesia
- Major side effects of levodopa therapy include which of the following?**
 - nausea, vomiting, anorexia and orthostatic hypotension
 - abnormal liver function tests
 - bradykinesia and tremor
 - dry eyes and dry mouth
- Which class of medications is associated with compulsive behavior?**
 - COMT (catechol-O-methyltransferase) inhibitors
 - memantine
 - dopamine agonists
 - MAO (monoamine oxidase) inhibitor
- Amantadine is a useful medication in the treatment of dyskinesias in Parkinson Disease. What side effect limits its use in the elderly?**
 - diarrhea
 - sialorrhea
 - dyskinesias
 - neuropsychiatric and cognitive effects
- Which is the only FDA approved medication for amyotrophic lateral sclerosis?**
 - memantine
 - lamotrigine
 - riluzole
 - coenzyme Q10
- What are the major factors that influence patients in their decision to take riluzole in the United States?**
 - cost of the medication and opinion of the physician
 - medication interaction and dosing regimen
 - side effects
 - size of the tablet

- 8. Memantine and riluzole exert their neuroprotective effects by what proposed mechanism?**
- inhibiting superoxide dismutase
 - inhibiting glutamatergic excitotoxicity
 - inhibiting caspase activity
 - inhibiting mitochondrial injury
- 9. Memantine is approved for use in which disease?**
- moderate to severe Huntington disease
 - early stages of Huntington disease
 - moderate to severe Alzheimer disease
 - early stages of Alzheimer disease
- 10. In a patient with Alzheimer disease, what is the ideal class of medication for the treatment of depression?**
- tricyclics
 - selective serotonin reuptake inhibitors
 - anticholinergics
 - neuroleptics
- 11. Hallucinations in Parkinson disease would ideally be treated with which of the following medications?**
- haloperidol
 - thorazine
 - nortriptyline
 - clozaril
- 12. Which medication is currently FDA approved for the treatment of pseudobulbar affect in ALS?**
- dextromethorphan/quinidine
 - SSRI antidepressants
 - tricyclic antidepressants
 - none of the above
- 13. In ALS patients, sialorrhea can be a major symptom as bulbar weakness worsens. Which of these medications is ideal for a patient with swallowing difficulty?**
- amitriptyline
 - scopolamine
 - diphenhydramine
 - glycopyrrolate
- 14. Which one of these medications are used to treat chorea in Huntington disease?**
- risperidone
 - levodopa
 - fluoxetine
 - bupropion
- 15. Sildenafil citrate is effective in treating erectile dysfunction in several neurodegenerative diseases. What side effect can this medication cause in Parkinson disease?**
- bradykinesia
 - tremor
 - orthostatic hypotension
 - chorea
- 16. Proposed mechanisms in neurodegenerative diseases include all of the following EXCEPT:**
- oxidative stress
 - apoptosis
 - inflammation
 - excess GABA
- 17. Which of the FDA approved therapy for Multiple Sclerosis is currently being studied in ALS?**
- alpha-interferon
 - beta-interferon
 - glatiramer acetate
 - corticosteroids
- 18. Phase II clinical trials of beta amyloid immunization in Alzheimer disease were interrupted because:**
- patients vaccinated with the immunization developed aseptic meningitis
 - immunization supplies were not sufficient
 - the trial was not randomized and blinded
 - patients developed reaction at the site they received the immunization
- 19. Which of these medications investigated in neurodegenerative diseases is/are no longer recommended for treatment?**
- remacemide
 - minocycline
 - insulin growth factor
 - ceftriaxone
- 20. Which of the following antioxidants have been shown in randomized, placebo controlled trials to be beneficial in any of the neurodegenerative diseases is no longer recommended for treatment?**
- vitamin E
 - n-acetylcysteine
 - selegiline
 - none of the above

Multiple Sclerosis

M. Patricia Leuschen, Kathleen M. Healey, and Mary L. Filipi

Keywords EAE; Gadolinium; Glatiramer acetate; IFN β -1a; IFN β -1b; Mitoxantrone; Natalizumab; Neuromyelitis optica; PASAT; Sclerosis

40.1. Introduction

New therapies challenge the very definition of multiple sclerosis (MS). By classic definitions, MS is a chronic neurological disease characterized by plaques or scars in the central nervous system (CNS) as a result of demyelization and atrophy of neuronal axons. However, for most diagnosed with MS, symptoms and progression are much more heterogeneous than that definition would imply. For most with MS, the initial symptoms include a relapsing and remitting inflammatory phase (RR-MS), which responds to immunotherapy. Natural history studies of clinical relapse rates, a primary endpoint used in most phase III treatment trials, report incidence of relapses from 0.5 to 2 per year (Weinshenker and Ebers, 1987). With time, most RR-MS patients transition to what has been characterized as a non-inflammatory secondary progressive form of the disease (SP-MS). Immunotherapies that target the inflammatory phase of MS may not be effective once the transition occurs. In addition, a proportion of those diagnosed with MS exhibit a more aggressive form of MS that does not show significant remission cycles nor respond to the same therapies. This aggressive form of the disease was termed primary progressive (PP-MS) using consensus data from an international survey of clinicians for standard definitions of these common clinical MS courses (Lublin and Reingold, 1996).

40.1.1. Therapeutic Options and Disease Definitions

Luccinetti's group (Lucchinetti et al., 1996; Lucchinetti et al. 2000) changed the way MS disease classifications were viewed when their pathologic studies confirmed that MS plaques differ. Neuroimmunologic evidence now suggests

that axonal transaction can precede demyelination rather than occur as a result of it (Trapp et al., 1998; Bitsch et al., 2000; De Stefano et al., 2001; Tsunoda and Fujinami, 2002). Changes in the CNS are associated and most likely precede measured disability by years and possibly decades. Central to these theories about MS is the disconnected temporal relationship between pathological changes in the CNS and disability (Bjartmar and Trapp, 2001). As therapeutic options for MS are reviewed, recent progress in standardizing outcome measures for both evaluating acute inflammatory relapses and long term progression will be discussed. There is no disagreement that the ultimate goal is to develop therapies that prevent disability associated with MS. As the heterogeneity of the disease is better understood, the ability to tailor therapy should also improve.

A definitive diagnosis of MS historically centers on clinical verification of two or more episodes (relapses or exacerbations) separated by time and space and involving separate systems such as optic neuritis and motor involvement of lower limbs (Poser et al., 1983). New guidelines were developed in 2001 by an International Panel on the Diagnosis of Multiple Sclerosis and are known as the "McDonald criteria" (McDonald et al., 2001). For a definitive diagnosis of MS, the McDonald criteria focus on demonstration of lesions in time and space but integrate MRI findings with clinical and diagnostic methods. Worldwide debate over the use of the McDonald criteria led to the convening of a second panel in Amsterdam in 2005 and revisions to the criteria now termed the 2005 Revisions to the McDonald Diagnostic Criteria for MS (Polman et al., 2005). The core of the MS diagnosis remains the clinically objective demonstration of typical disease signs and symptoms in time and space supported by laboratory evidence including MRI. Debate over definitions is important to the development of MS therapies since FDA guidelines insist on clinical outcome measures such as a change in the number of relapses and the time between relapses. Validated qualitative or quantitative outcome measures that specifically define a relapse do not exist.

Initial diagnosis is not the only moving target in defining MS. Debate also continues on when diagnostic criteria support

a diagnosis of PP-MS (Thompson et al., 2000) and when or if clinically isolated syndromes such as monosymptomatic optic neuritis convert to MS (Barkhof et al., 1997; Filippi et al., 1994; Jacobs et al., 2001).

40.1.2. Diagnosis and Disease Activity Measures

The level of disability in MS is usually scored using the Kurtzke expanded disability status scale (EDSS), a 10 point scale biased toward motor function (Kurtzke, 1983, 1991). With the addition of 0.5 point steps, the Kurtzke EDSS is often applied with 19 intermediate steps where 0 represents no disability. The lower ratings in the scale are based upon the neurological exam; mid and higher rating scores are based on ambulatory ability and performance of activities of daily living. Data on the average time MS patients remain at a specific EDSS level were published prior to FDA approval of the current therapies (Weinshenker et al., 1991) and illustrate that time at any specific point on the scale is highly variable. Even so, the EDSS is a primary outcome measure in all phase III trials of MS immunotherapies.

The Multiple Sclerosis Functional Composite (MSFC) was developed by the MS Consortium (Whitaker et al., 1995) for evaluating disabilities ranging from motor function to cognitive changes and to replace the EDSS. The three tools included in the MSFC are a timed 25 foot walk, the 9-hole peg test for hand dexterity and the Paced Auditory Serial Addition Test (PASAT). The MSFC is a quantifiable measure of disability but ten years later, it is still infrequently incorporated as a primary outcome measure because of the increased time element necessary to validate the individual tests and the time necessary for their administration.

As a technology, MRI is invaluable in providing information that has greatly advanced knowledge of the disease process of MS. Ian Young is credited with the first image of an MS lesion using MRI and fortuitously predicted that this technique could also measure disease severity and serve as a monitor for effectiveness of treatments (Young et al., 1981). Approximately five years later the contrast medium, gadolinium (Gd) was introduced. This method of injecting a contrast material intravenously is able to demonstrate breach of the blood-brain barrier (BBB) indicating newly acquired active inflammatory lesions of MS (Grossman et al., 1988). It was later verified that extensive sub-clinical activity evidenced by Gd enhancing lesions occurs in the absence of clear relapses or disease worsening at a ratio of 10–15:1 (Isaac et al., 1988; Willoughby et al., 1989; Khoury et al., 1994; Thompson et al., 1992). MRI is now a primary endpoint in phase I and II treatment trials and as a secondary endpoint in phase III trials.

Serial MRI documents that clinical MS exacerbations are associated with focal BBB damage. As early as 1965, experimental allergic/autoimmune encephomyelitis (EAE) animal models revealed lymphocyte adherence to post capillary venules and subsequent migration into CNS parenchyma preceding demyelination (Lampert and Carpenter, 1965). Both

serial MRI in MS patients and EAE animal studies support the role of an inflammatory, neuroimmunologic response in the disease. MRI findings during the early stages of MS demonstrate the presence of active inflammatory lesions in the brain or spinal cord (Bjartmar and Trapp, 2003). Axonal injury begins at disease onset and correlates with the degree of inflammation within lesions. This axonal loss remains clinically silent for many years and irreversible neurological disability develops when a threshold of axonal loss is reached and compensatory CNS resources are exhausted. The ratio of silent inflammatory sub-clinical lesions to clinical relapses is reportedly 5–10:1 (Bjartmar et al., 2003; Miller, 2004). This discovery of silent lesion accumulation was instrumental in pushing research for the treatment of MS to the forefront in an attempt to decrease lesion accumulation and subsequent disability progression (Bjartmar and Trapp, 2003). However, the monitoring of disease progression by MRI or quantifying clinical symptoms is not adequate. The presence of MRI lesions correlates poorly with clinical symptoms and does not fully predict or define the level of disability or disease activity. Molecular evidence indicates a continuum of dysfunctional homeostasis and inflammatory changes between areas of lesions and normal appearing white matter. This continuum supports the hypothesis that MS is a generalized process that involves the entire CNS (Lindberg et al., 2004). MS may be active in normal appearing white matter but may not be detectable by current levels of testing.

40.1.3. Emerging Immune Modulators

Prior to the early 1990s, there was no Food and Drug Administration (FDA) approved disease-modifying agents for treatment of any form of MS. In the past ten years, five agents received FDA approval; four are immunomodulators for treatment of RR-MS and one, mitoxantrone, is an immunosuppressant. MS is now a treatable disease. In their Disease Management Consensus Statement (NMMS, 2005), the National Multiple Sclerosis Society (NMMS) recommends that initiation of an immunomodulator should be considered as soon as possible following a definite diagnosis of active MS. The NMMS data also indicate that only 38% of patients with RR-MS are currently on immunomodulatory therapy.

The phase III trials for currently approved MS immunotherapies followed the use of the therapy for 20 months or less. Long term efficacy and compliance can be an important factor since historic data show that people with MS lived on average 35 years following diagnosis even before current therapies (Smith and McDonald, 1999). Usually MS only decreases life expectancy by 2–3 years. However, prior to the advent of current therapies, 50% of those with MS needed assistance (a cane to walk over one half block) 15 years after diagnosis (Weinshenker et al., 1989).

Four of the five current immunomodulatory therapies are only approved for RR-MS and have not shown effectiveness in non-inflammatory SP-MS or more aggressive forms of the

disease. MS has been regarded as a single disorder with clinical variants, but there is strong evidence that it may comprise several related disorders with distinct immunological, pathological and genetic features (Compston, 1997). To support this theory, research indicates the demyelination; neuronal atrophy and axonal destruction follow different pathogenetic pathways in subgroups of MS patients (Lassmann, 2001).

The disease, MS, usually does not affect peripheral myelin. There are, however, cases of disease clinically and pathologically indistinguishable from MS in which there is peripheral demyelination in a pattern resembling chronic inflammatory demyelinating polyneuropathy. MS has extremely heterogeneous patterns, with potentially devastating clinical manifestations in some individuals while others have very little progression or disability. Early in the disease, the typical clinical course of MS consists of variable relapsing-remitting symptomatology. While the majority of those with MS at this inflammatory stage respond to immunotherapy with interferon (IFN) β -1a, IFN β -1b or glatiramer acetate, some patients do not.

Natural history studies (Smith and McDonald, 1999), prior to the new therapies show that after 10–15 years the highly inflammatory RR-MS pattern transitions to a more chronic, less inflammatory progressive phase. This chronic phase is characterized by increasing disability with less discreet relapse episodes and a more constant downhill disability course. MS itself has the propensity to dissipate or slow after 20–25 years duration but disability will continue to progress (Paty et al., 1997). Therapies aimed at the inflammatory phase of RR-MS do not halt the less inflammatory progressive phase. This is hypothesized to be due to previously accumulated lesion load within the CNS and the circuitous nature of disability building on disability. With the degree of heterogeneity, a frequent recurrent problem is how to fit the MS treatment to the individual patient's symptoms and progression. The success and approval of immunosuppressant therapy with mitoxantrone for that subgroup of MS patients with aggressive inflammatory disease supports the concept that the immune aspects of MS are heterogeneous and that treatment must be tailored to specific disease course.

A similar approach meeting with success is with neuromyelitis optica or Devic's syndrome. While uncommon, neuromyelitis optica preferentially affects the optic nerve and spinal cord. While resembling MS, diagnosis is confirmed by its clinical severity, an MRI pattern with normal brain findings but extensive lesions in the spinal cord, and CSF analysis of polymorphonuclear pleocytosis and no oligoclonal banding. A serum autoantibody marker, NMO-IgG is highly specific for the syndrome (Wingerchuk and Weinshenker, 2005) and the syndrome appears to have a strong humoral component. Open label trials with small numbers of patients indicate that therapy with rituximab, a chemotherapeutic drug that depletes the B cell population is effective in slowing the relapse rate (Cree et al., 2005).

40.2. Historical Therapies for MS

40.2.1. Hypothetical Benefits Without Improved Clinical Outcomes

40.2.1.1. Interferon γ (IFN γ)

In the 1980s, studies with EAE, an animal model mimicking MS, indicated that interferon γ (IFN γ) was effective in treating that disease and a trial was initiated to evaluate its potential benefit in human MS. Rather than showing efficacy, in 1987, use of IFN γ as a therapy in MS patients caused an increase in clinical exacerbations and forced the clinical trial to terminate early (Panitch et al., 1987). Associated study of IFN γ in 20 MS patients indicates increased concentrations of IFN γ and TNF α precede the observation of clinical defects (Beck et al., 1988). An evaluation of primary RR-MS patient lymphocytes using flow cytometry supports a correlation between EDSS scores and IFN γ secretion (Petereit et al., 2000). Intracellular cytokine immuno-staining of anti CD8+ T cells reveals a correlation with IFN γ and disease phase but not disease activity (Becher et al., 1999). What initially seemed efficacious in the EAE animal model, not only did not decrease MS symptoms but is now felt to be a marker of active inflammatory disease.

40.2.1.2. Histamine

In the 1950s and 1960s, immune therapies including histamine were evaluated and shown to have no significant benefit in decreasing the clinical or laboratory parameters associated with active MS. One variation of a therapy including histamine is still available as a trans-dermal gel patch with a proprietary blend of histamine and caffeine now termed Prokarin. Prokarin was formerly known as "Procarin." The revised spelling was adopted to avoid potential conflicts with another existing trademark. A small double blind pilot study shows Prokarin has a modest effect on fatigue associated with MS but no change in the Multiple Sclerosis Functional Composite (MSFC) (Gillson et al., 2002). Since the trial was only 12 weeks, relapse rate and MRI data were not evaluated. Prokarin use for MS has not been evaluated by the FDA.

40.2.1.3. From Placebos to Bee Stings

No review on therapies for MS would be complete without some mention of the placebo effect and the vast underlying anecdotal stories of agents and treatment with immune effects and hypothetical benefits. Because relapse rates can be relatively low, less than one per year and because fatigue is the single most commonly reported symptom, the placebo effect in many early therapy trials is significant. In addition, reports of MS patients using untested therapies such as daily or weekly exposure to bee stings or removal of all metal teeth fillings continue to appear. Since MS is now treatable with FDA approved therapies, the ability to evaluate such evidence has become problematic.

40.2.2. Beneficial Immune Therapies: Use of Steroids for Acute Episodes RR-MS

Historically, steroids and ACTH have been used in the treatment of MS relapses. While both suppress cell mediated and humoral immune responses, the major effect in MS acute relapse is to suppress inflammation. A meta-analysis of randomized controlled clinical trials (Brusaferri and Candelise, 2000) indicates that any type of steroid or ACTH treatment significantly accelerates short-term recovery from an acute MS relapse. However, there is no evidence that steroids reduce the risk of an MS relapse. A randomized trial of oral versus intravenous (IV) methyl prednisolone for treatment of acute relapses of MS shows no clear advantage of either treatment route (Barnes et al., 1997). Currently methyl prednisolone is considered standard of care for acute MS relapses. Methyl prednisolone (Solu-Medrol) is used with IV treatment for 3–5 days at 500–1000mg/day. Methyl prednisolone IV therapy may be followed by a oral prednisone taper. The use of low dose oral prednisolone is also effective in conjunction with INF β therapies when flu-like side effects persist.

40.3. Immunotherapies for RR-MS

40.3.1. FDA Approval of IFN β -1a, IFN β -1b, and Glatiramer Acetate for RR-MS

While no cure for MS is known, the FDA approves four immunotherapies for RR-MS. All shorten attacks and lengthen the time between attacks by ~30% (Arnason, 1999a, 1999b). The therapies include variations of IFN β : IFN β -1a, (Avonex and Rebif) and IFN β -1b (Betaseron). The second type of immunotherapy, glatiramer acetate is a copolymer of four amino acids termed Copaxone. All approved therapies involve self

injections or injections by a caregiver and are accompanied by side effects.

40.3.1.1. FDA Trials and Their Outcome Measures

The FDA phase III trials leading to approval of the two forms of IFN β 1a, IFN β -1b and glatiramer acetate for RR-MS used clinical outcome measures such as the number of relapses over a 12 month period as the primary outcome measure for efficacy of the therapies. Along with decreasing the relapse rate, both the IFN β s and glatiramer acetate increase the time between relapses and decrease lesion load on MRI. Since all comparisons between therapies are post-market, the classifications developed by Goodlin (Goodlin et al., 2002) will be used when making comparisons. The longest Class I pivotal trial for an MS drug was up to 36 months (m) for glatiramer acetate (Johnson et al., 1995; Johnson et al., 1998) while the shortest averaged 20m for intramuscular (IM) IFN β -1a (Avonex) (Jacobs et al., 1996). Formulation, dosing schedules and inclusion criteria differed in the pivotal trials and in the analytical methods used in the trials but the basic outcomes (a decrease in relapses and relapse rate) can be compared according to clinical and MRI findings (Johnson, 2005) (Figure 40.1). All four therapies for RR MS reduce the relapse rate but one, IFN β -1b did not show a significant reduction in disability (The IFN β MS Study Group, 1993). MRI outcomes are also positive with a decreased overall burden of disease in three of the four therapies for RR MS. However, IFN β -1a (Avonex) did not show the MRI effect at 2 years (Jacobs et al., 1996). Gd enhancing lesions was not an outcome measure in the initial clinical trial of IFN β -1b but was significant for the other three trials (Johnson et al., 1995; The IFN β MS Study Group, 1993; PRISMS-Study Group, 1998).

Mitoxantrone (Novantrone) approved by the FDA in 2000, is the only drug approved for treatment of MS once transition

FIGURE 40.1. Relapse Rate Reduction, Phase III Studies (Class I). In the pivotal Class I studies of disease-modifying drugs for multiple sclerosis, glatiramer acetate (GA) and higher-frequency (three times weekly) dosing of interferon beta were clearly superior to once-weekly interferon (IM) in reduction of relapse rate. Johnson et al. *Neurology*, 1995.³ Jacobs et al. *Ann Neurol*, 1996.⁵ IFNB Study Group. *Neurology*, 1993.⁶ PRISMS Study Group. *Lancet*. 1998.⁷ (Adapted from Johnson, 2005).

to the progressive form occurs. Use of mitoxantrone and similar therapy will be discussed in a subsequent section.

40.3.1.2. *Side Effects and Compliance*

When IFN β therapies were first approved by the FDA for treatment of RR-MS, flu like symptoms were known side effects but consistently described as minimal and transient. However, in the early pivotal trials for IFN β -1b, a significant number of patients withdrew for drug toxicity issues that were often consistent with flu-like symptoms (The IFN β MS Study Group and The U British Columbia MS/MRI Study Group, 1995). Use of IFN β is now a mainstay of successful long term MS therapy. "Long term" therapy is the key point because, unlike many neurologic diseases, MS is usually diagnosed in young adults and does not significantly decrease life span. Adherence and long term compliance are serious issues particularly for those patients who continue to experience side effects to IFN β injections. It is now known that flu-like side effects are common in RR-MS patients injecting IFN β and are as high as 90% in patients initiating therapy. Use of step wise gradual escalation of dosing when initiating IFN β is standard of care in virtually all MS Centers as a means of decreasing this side effect. In 1999, Rice's group evaluated gradually introducing use of IFN β with or without ibuprofen and reported that the combination did reduce flu-like symptoms (Rice et al., 1999). Ibuprofen was also evaluated against paracetamol and found to be equally effective in managing the flu-like symptoms of IFN β therapy (Reess et al., 2002). In a letter to the editor, Rio (Rio, 2000) supports the gradual introduction of IFN β and use of ibuprofen but also suggests use of oral low dose steroids to minimize side effects. A randomized open label study of naproxen, acetaminophen and ibuprofen for controlling the side effects of IFN β -1a, shows naproxen and ibuprofen are more effective than acetaminophen in reducing the physical side effects. None of the study pain medications were effective in minimizing fatigue or muscle aches and pain in those MS patients on IFN β -1a who had continued to report side effects after >6 m of therapy (Leuschen et al., 2004). In a 1997 study, Munschauer and Kinkel (1997) recommend acetaminophen as the first line adjunct therapy for IFN β associated flu like symptoms. The package insert for IFN- β -1a suggests use of pain medications specifically mentioning acetaminophen but with no specific guidelines. Finally, indomethacin was shown to reduce the side effects of IFN therapy in a study by Mora et al. (1997).

For those RR MS patients whose flu-like symptoms, fatigue or significant muscle and joint pain persist while on IFN β therapies, use of low dose oral corticosteroids is another option (Rio, 1998; Martinez-Cacenes, 1998).

40.3.1.3. *MRI and Bioimaging to Evaluate Clinical Efficacy*

Brain atrophy is recognized as a reproducible outcome measure of destructive change in MS. Significant atrophy

changes occur within 9–12 months of disease onset in RR-MS in patients treated with the immunomodulators (Hardmeier et al., 2003). This atrophy is detectable even earlier in untreated patients. A direct short-term relationship between inflammation and development of brain atrophy is indistinct, possibly due to the time lag while tissue degradation occurs and lack of testing available that is sensitive enough to pick up minor changes (Hardmeier et al., 2003). It is well documented by MRI that individuals with MS develop varying degrees of brain atrophy, and maintain a 20% greater atrophy than the unaffected population. Previously, brain atrophy was considered a late occurring disease manifestation of MS. Zivadinos and Bakshi (2004) find that brain atrophy can be detected within 3 months of diagnosis. Current thinking is that brain atrophy occurs with normal changes associated with aging, but is considered accelerated if it reaches levels >0.5–1% per year.

Brain atrophy, particularly central atrophy, correlates more closely to increased cognitive impairment than MRI lesion burden. This may be explained in part by atrophy of the thalamus, a deep gray matter structure that mediates cognitive function via cortical and subcortical pathways (Benedict et al., 2004) and by cortical atrophy of the frontal cortex. The frontal cortex atrophy can predict neuropsychological impairments in verbal learning, spatial learning, attention and conceptual reasoning. The regions of the cortex most susceptible to atrophic and cognitive changes in MS are the right and left superior frontal lobes (Benedict et al., 2004). In a related study, MRI brain atrophy was evaluated as a secondary outcome measure in a small group of patients following stem cell transplant for MS (Healey et al., 2004). That study shows ventricular atrophy and thickness of the corpus callosum is a mild but significant correlation to disability. Simon et al. (1999) confirm that substantial neocortical volume loss occurs in MS patients and suggests that neocortical gray matter pathology may occur early in the course of the disease, contributing significantly to neurologic impairment. Although a proportion of this pathology may be secondary to white matter inflammation, the extent of the change suggests that an independent neurodegenerative process is also active.

While many MRI parameters do not correlate well to disability, the presence and degree of atrophy does reflect level of disability. MRI reveals that brain and spinal cord atrophy occur early in the course of MS, far earlier than originally anticipated (Zivadinos and Bakshi, 2004). The degenerative nature of the disease shows increased CNS plaquing with subsequent increases in T1 black holes, T2 total lesion load, and finally increases in brain atrophy. This has important implications for early treatment, as atrophy is thought to reflect destructive, irreversible pathology and sub clinical impairment if not overt disability (Simon, 2001). The assessment of brain volume changes on serial MRI can provide an objective measure of progressive atrophy, reflecting the neurodegenerative component of MS pathology and the long-term efficacy of MS therapies.

40.3.1.4. Clinical Responses for SP-MS and PP-MS

The diagnosis of PP-MS remains particularly challenging and its pharmacologic management remains a challenge (Doskoch, 2005). Several clinical trials have focused on these patients and while no treatment efficacy has been demonstrated, information is helping to define this sub group of MS patients. The largest trial (PROMise) began recruitment in 1999 (Wolinsky et al., 2005). Inclusion criteria included progressive neurologic symptoms for at least 6 months with no history of prior exacerbations or a RR pattern. EDSS scores ranged from 3.0 to 6.5 and all patients were screened by MRI for definitive MS. Over 60% of the study group met the classification for definitive PPMS by McDonald criteria. The treatment protocol included glatiramer acetate (20 mg/d) or placebo with a planned 16m enrollment. The study was terminated in 2002 (Wolinsky et al., 2004). At that point, 37 patients had 41 relapses or 2% per year. Only 14% of the patients with Gd enhanced lesions had a twofold increased risk of relapses. More significant than the low relapse rate was the low rate of progression. With a study prediction rate of 50% among the least effected patients (EDSS 3.0–5.0), the progression rate was actually 16% at 1 year and 28% at 2 years. The unexpectedly slow rate of progression changed the trial's statistical power to detect even a modest therapeutic benefit from use of glatiramer acetate. This slower rate than expected of progression in PP-MS is also reported by E. Waubant for a clinical trial of mitoxantrone and one for IFN β -1a discussed at the 19th Annual Meeting of the Consortium of Multiple Sclerosis Centers (Doskoch, 2005). These data support redefining the diagnosis of PP-MS and include the presence of Gd enhanced lesions, positive CSF findings and a high T2 burden of disease as predictors of faster progression (Wolinsky et al., 2004).

Current phase I/II trials in PP-MS are underway and include evaluation of rituximab, a synthetic antibody that binds to and induces lyses of B cells. The trial is scheduled to enroll over 430 patients for 30m and will monitor clinical outcomes as well as immunologic and MRI measures. Rationale for the trial is based on the efficacy in use with worsening Devic's disease or neuromyelitis optica (Cree et al., 2005).

40.3.2. EAE Animal Models for MS Therapy Development

The animal model for MS, EAE was introduced in 1933 to study CNS reactions to vaccines including measles, small pox and rabies. Although the initial studies were done in monkeys, most studies on MS have used mice. Over time the model has evolved into adoptively transferring myelin basic protein auto reactive T cells into an animal. These programmed T cells cross the BBB producing inflammatory lesions in the CNS as seen in MS. Animals develop functional deficits quickly and in mice scoring of "disability" is done by a 5 point scale. The EAE model continues to be used to investigate new therapies for MS in preclinical testing. However the assumption that

this animal model should be central to theory of causation and treatment for MS has been questioned since inception. More recently, EAE models were critically challenged when tissue biopsy of very early MS lesions of seven hour duration exhibited an absence of autoimmune cells within the lesion (Barnett and Prineas, 2004).

While the EAE model has pitfalls, perivascular T cell reactions do mediate the demyelinating process associated with MS when immunologically active cells enter the CNS via activated endothelium (Dorovin-Zis et al., 1992). Myelin is destroyed either as a non-specific reaction by the release of lymphokines, or by antigen specific mechanisms. Several lines of evidence support the primary nature of the inflammatory process in MS. Serial MRI studies reveal that clinical MS attacks are associated with focal BBB damage (Grossman et al, 1988; Kennedy et al., 1988). In the animal model EAE, it is well documented that T cells adhere and subsequently migrate across the cerebrovascular endothelium into the CNS parenchyma where demyelination occurs (Lampert and Carpenter, 1965; Raine, 1994). Activated CD4 + T cells are typically present in MS lesions in areas of active myelin breakdown. In older plaques, gamma delta TCR + T cells are more frequent (Selmaj et al., 1991). Less information is available on when or why there is a shift in the type of T cells present at the demyelination sites as the disease progresses. In addition, recent attention has turned to a role for B cells particularly in aggressive forms of MS.

40.3.3. Failed Clinical Trials

40.3.3.1. Tysabri (Natalizumab)

The aftermath of recent clinical trials (Miller et al., 2003), FDA approval (FDA Consum, 2005a) and then withdrawal (FDA Consum, 2005b) after several cases of progressive multifocal leukoencephalopathy were attributed to treatment with Natalizumab (Tysabri) (Langer-Gould et al., 2005; Kleinschmidt-DeMasters and Tyler, 2005) illustrate the promise and the pitfalls of carrying new MS therapies to the marketplace. Tysabri (natalizumab) is a recombinant humanized monoclonal antibody that binds to α 4-integrin. The α 4 subunits of α 4 β 1 and α 4 β 7 integrins are expressed on the surface of all leukocytes except neutrophils and inhibit the α 4 mediated adhesion to their receptors. The α 4 family of integrins includes vascular adhesion molecule-1 (VCAM-1), which is expressed on activated vascular endothelium. Rationale for its use centered on data that binding prevents transmigration of leukocytes across the cerebrovascular endothelium into inflammatory brain parenchyma. Evidence also supports a role for Tysabri in inhibition and further recruitment of activated T cells (Rice et al., 2005).

In the phase II trial, all Natalizumab treated MS subjects had fewer relapses and fewer Gd enhancing lesions compared to placebo treated subjects (O'Connor et al., 2005). An open label safety and drug interaction study of the use of Natalizumab

(3.0 or 6.0 mg/kg IV) in combination with IFN β -1a (30 μ g IM) found the drug combination generally well tolerated (Vollmer et al., 2004) and had set the stage for larger clinical trials of combination therapies. Even the title of the March-April, 2005 FDA approval report (FDA Consum, 2005a) "New treatment, new hope for those with multiple sclerosis", implied a new approach and drug class with promise for MS and other autoimmune disease. Within two months (FDA Consum, 2005b), the FDA had withdrawn Natalizumab (Tysabri). Reports of progressive multifocal leukoencephalopathy following treatment with Natalizumab (Tysabri) appeared in the summer of 2005 (Langer-Gould et al., 2005) followed by reports of similar findings in the combination Natalizumab and IFN β -1a trial (Kleinschmidt-DeMasters and Tyler, 2005).

40.4. FDA Approved Therapies for MS

All three IFN- β products (Avonex, Rebif, and Betaseron) are approved by the FDA for the treatment of RR-MS. There is variability in IFN- β preparations, administration and their side effects. All produce a similar decrease in relapse rate of ~30% and increase the time between relapses in RR-MS. IFN- β has also been associated with teratogenic effects. Adequate birth control and pregnancy testing are recommended for all women with child bearing potential prior to initiation of any of the IFN β therapies. Since MS is a disease frequently diagnosed in young adults and with an increased incidence in women, pregnancy testing and reporting is required for all women on the IFN β s.

40.4.1. IFN β -1a, (Avonex)

40.4.1.1. *Nomenclature, Approved Dosing Format, and Dosing Schedule*

Avonex was the initial form of IFN β -1a approved by the FDA for use in the United States (Jacobs et al., 1996). The recommended dosing schedule is a once a week IM injection. IFN- β 1a. IFN β -1a (Avonex) is supplied as a liquid in single use vials or syringe at the dose of 33 mcg IFN- β 1a. The vial also contains 16.5 mg albumin (human), 6.4 mg sodium chloride, 6.3 mg dibasic sodium phosphate and 1.3 mg monobasic sodium phosphate. Of the approved IFN β therapies, this drug has the lowest dose and longest inter-dosing interval.

40.4.1.2. *Adverse Effects of IFN β -1a (Avonex)*

The most common side effects of IFN β -1a (Avonex) involve flu-like symptoms including headache, fever, chills, muscle or joint ache, fatigue, pain or injection site inflammation. Initiation of therapy in a step-wise increase in dose and use of pain medications usually alleviate or substantially decrease these side effects. Less common side effects include nausea, stomach upset, diarrhea, a lower red blood cell count, sleep disturbances, dizziness, and infection. As with other IFN β

therapies, which are all classified as Category C, female patients are warned that the therapy has not been evaluated as a human teratogen or during breast feeding.

40.4.1.3. *Post Approval Efficacy*

A post-approval study evaluated the use of IFN β -1a following a first demyelinating event when a clinically definitive diagnosis of MS was still not confirmed (Jacobs et al., 2001). Clinically definite MS is defined as two clinical attacks either with clinical evidence of two lesions or clinical evidence of one lesion plus para-clinical evidence (MRI, EEG or CSF changes) of a second lesion. The Controlled High Risk Subjects Avonex Multiple Sclerosis Study (CHAMPS) followed 385 participants in two sub-groups: a placebo group and a group receiving IFN β -1a. CHAMPS found that initiating therapy with IFN β -1a at the first demyelinating event is beneficial for patients with evidence of brain lesions on MRI that indicate a high risk of developing clinically definite MS (Jacobs et al., 2001). After 18 months, the median increase of lesion volume in participants receiving IFN β -1a therapy was 1%, while it was 16% among participants in the placebo group. After three years, the likelihood of participants in the IFN β -1a group developing clinically definite MS was 35% as compared to 50% in the placebo group (Beck et al., 2002).

The CHAMPS findings provide strong evidence that an IFN β -1a regimen could be instrumental in delaying the progress of the disease, both by lengthening the time before demyelinating events progress to the level of clinically definite MS and by slowing the effects after a definite diagnosis. CHAMPS also provided data on IFN β -1a side effects. Within the first six months of the trial, 54% of the IFN β -1a group reported flu-like symptoms, while 26% of those in the placebo group experienced the same (Jacobs et al., 2001).

40.4.2. IFN β -1b (Betaseron)

40.4.2.1. *Nomenclature, Approved Dosing Format, and Dosing Schedule*

IFN β -1b (Betaseron) is a purified protein produced by recombinant DNA technology with 165 amino acids and approximate molecular weight of 18,500 daltons. Lyophilized vials contain 0.3 mg IFN β -1b with mannitol (15 mg) and albumin (15 mg) as stabilizers. Reconstitution with the diluent supplied produces a 0.54% sodium chloride solution. IFN β -1b or Betaseron is also dispensed in a pre-filled syringe at a dose of 22 μ g (6MIU) per dose for 66 μ g/week. A higher dose of 44 μ g (12 MIU) per dose for 132 μ g per week is also available. The recommended dosing schedule is three times a week as a subcutaneous injection.

40.4.2.2. *Adverse Effects of Betaseron (IFN- β -1b)*

The most serious adverse reactions are depression, suicidal ideation and injection site necrosis. A single case of suicide, potentially due to depression, was reported in the initial phase

III trial of IFN β -1b. The incidence of depression of any severity was 34% in the phase III clinical trial (The IFN β MS Study Group, 1995). Injection site necrosis was reported in 5% of patients in the early controlled trials. The most commonly reported adverse reactions to IFN β -1b (Betaseron) are lymphopenia, (lymphocyte count <1500/mm³), injection site reaction, asthenia, flu-like symptom complex, headache, and pain. The most frequently reported adverse reactions resulting in some clinical intervention, usually discontinuation of therapy or adjustment in dosage, were depression, flu-like symptom complex, injection site reactions, lymphopenia, increased liver enzymes, asthenia, hypertonia and myasthenia. As with other IFN β therapy, female patients are warned that the therapy has not been evaluated as a human teratogen or during breast-feeding.

40.4.2.3. Mechanism of Action

The specific mechanism of action of IFN β -1b in RR-MS is essentially unknown. Immunomodulatory effects of IFN β -1b include enhancement of suppressor T cell activity, reduction of pro-inflammatory cytokine production, down regulation of antigen presentation and inhibition of lymphocytes trafficking across the BBB.

40.4.3. IFN β -1a (Rebif)

40.4.3.1. Nomenclature, Approved Dosing Format, and Dosing Schedule

Rebif is the second IFN β -1a product. This form of IFN β -1a is a purified 166 amino acid glycoprotein with a molecular weight of ~22,500 daltons. As with Avonex, Rebif is produced by recombinant DNA technology from the genetically engineered human IFN β gene. Rebif is formulated as a sterile solution in a pre-filled sterile syringe intended for subcutaneous injection, three times each week. Each 0.5 ml of Rebif contains either 22 mcg or 44 mcg IFN β -1a, 2 or 4 mg human albumin, 10.9 mg mannitol, 0.16 mg sodium acetate and water for injection. While a single subcutaneous injection of the lower dose of this form of IFN β -1a is below that of the IFN β -1a IM product, the three times per week dosing schedule raises it above the once weekly dose for the IM preparation.

40.4.3.2. Adverse Effects of Rebif (IFN- β -1a)

The most common side effects involve flu-like symptoms with headache, fever, chills, muscle or joint ache, fatigue, pain or injection site inflammation. Less common side effects include nausea, stomach upset, diarrhea, a lower red blood cell count, sleep disturbances, dizziness, and infection.

40.4.3.3. Efficacy

Class I evidence shows a statistically significant delay in the confirmed progression of disability with IFN β -1a IM and also

shows a statistically significant reduction in relapse rate in a 2 year placebo-controlled clinical trial (PRISMS, 1998). This form of IFN β -1a was available in Europe and Canada prior to approval by the FDA for use in the United States.

40.4.4. Glatiramer Acetate (Copaxone)

40.4.4.1. Nomenclature, Approved Dosing Format, and Dosing Schedule

Glatiramer acetate was termed copolymer-1 in early clinical trials. Glatiramer acetate is a synthetic compound made up of acetate salts of polypeptides that are found in myelin and contains four naturally occurring amino acids: L-glutamic acid, L-alanine, L-tyrosine, and L-lysine with an average molar fraction of 0.141, 0.427, 0.095, and 0.338, respectively. The average molecular weight of glatiramer acetate is 4,700–11,000 daltons. Copaxone is a sterile, lyophilized powder containing 20 mg of glatiramer acetate and 40 mg of mannitol that is supplied in single-use vials for subcutaneous administration after reconstitution with the diluent supplied (sterile Water for Injection) or in pre-filled syringes.

40.4.4.2. Side Effects of Glatiramer Acetate

Most common adverse effects in controlled trials include injection site reactions, vasodilatation, chest pain, asthenia, infection, pain, nausea, arthralgia, anxiety, and hypertonia. About 10% of patients experience an immediate post-injection reaction (flushing, chest pain, palpitations, anxiety, dyspnea, throat constriction, and urticaria). The symptoms are transient and self-limited, and usually do not require specific treatment. Transient chest pain was noted in 21% of Copaxone patients versus 11% in the placebo group with no long-term sequelae. Unlike therapy with the IFN β s, glatiramer acetate is not associated with flu-like symptoms.

40.4.4.3. Mechanism of Action and Efficacy

Glatiramer acetate is thought to stimulate T cells to change from harmful, pro-inflammatory cytokines to anti-inflammatory cytokines that work to reduce inflammation at lesion sites. In a two-year randomized, double-blind, controlled trial involving 251 ambulatory patients with RR MS, those taking the drug had a 29% reduction in annual relapse rate compared to subjects who were given a placebo (Johnson et al., 1998). Subsequent studies confirm the drug's long-term effectiveness in reducing the number and severity of exacerbations and demonstrate its ability to reduce the number of new, Gd-enhancing brain lesions on MRI (Johnson et al., 2000).

Follow up studies on glatiramer acetate show that the relapse rate continues to be lower after 6 years on therapy (Johnson et al., 2000). The last 3 years of the Johnson study were open label with the initial study a double-blinded protocol.

40.5. Therapies Approved for RR-MS

There are no Class I clinical trials by Goodlin criteria (Goodlin et al., 2002) comparing the approved therapies for RR-MS. The trials discussed in the following section are all post-marketing trials of relatively short duration. Even so, valuable information can be found if their shortcomings are remembered.

40.5.1. Glatiramer Acetate Versus IFN β -1a (IM) and IFN β -1b

Published head to head trials of the FDA approved therapies for RR MS still involve relatively small numbers and relatively short time periods but they provide important information on efficacy and side effect profiles. The first such study was a retrospective review by Kahn that was followed by a prospective open label 18-month study comparing IFB β -1a IM, IFN β -1b and glatiramer acetate (Khan et al., 2001a). The subcutaneous form of IFN β -1a (Rebif) was not FDA approved at the time. At the end of the 18-month prospective trial, 122 of 156 participants remained on their original therapy (79%). Relapse rate was the primary outcome measure. Participants on Glatiramer acetate had a significant reduction in relapses ($P < 0.0001$), as did those on IFN β -1b ($p < 0.001$) compared to untreated patients. There was not a significant difference in the relapse rate for the control patients and those on IF β -1a IM.

40.5.2. IFN β -1a (IM) and IFN β -1b

For the INCOMIN Trial, IFN β -1a (IM Avonex) was compared to IFN β -1b (Betaseron) in 188 MS patients with minimal baseline disability (EDSS of 1–3.5) (Durelli et al., 2002). The primary endpoint was the number of patients who remained relapse free during the 2 years trial. In this trial, 51% of MS patients who received IFN β -1b (Betaseron) remained relapse free compared to 36% for those who received IFN β -1a (IM Avonex) ($p = 0.036$). Disability status was also better for the IFN β -1b group with only 14% of patients progressing 1 or more EDSS step compared to 20% for those on IFN β -1a (IM). The INCOMIN Trial was one of the first to provide evidence that IFN β -1a in the higher dose and dosing schedule was more efficacious than a low dose given once weekly.

40.5.3. IFN β -1a Subcutaneous Versus IFN β -1a IM

IFN β -1a (Rebif) at 44mcg three times per week was more effective than IFN β -1a IM (Avonex) in reducing relapses and MRI activity over a 48 week study in a large North American and Candian trial of over 600 patients termed EVIDENCE (Panitch et al. 2002). A significant relapse and MRI activity reductions was reported in patients changing therapy from Avonex to Rebif over an average of 34 weeks. While the higher frequency subcutaneous dosing with Rebif showed a modest positive effect over the IM Avonex form of IFN β -1a,

a higher rate of liver toxicity was reported for the Rebif (18%) versus (9.8%) Avonex ($p < .003$) (Panitch et al., 2002). While verifying that higher dose and more frequent dosing of IFN β -1a is more effective, this trial brought to the forefront the liver toxicity side effects of the higher dose therapies.

40.5.4. Glatiramer Acetate Versus IFN β -1a Subcutaneous, IFN β -1a IM and IFN β -1b

Almost three hundred patients enrolled in the Haas (2003) prospective head to head study of all four FDA approved therapies for RR-MS. All four therapies show a significant reduction in relapse rate ($p < 0.02$ for the IFNs) with glatiramer acetate showing the most significant reduction ($p < .001$). Discontinuation rates were also higher on the IFN β s; 20–30% by 6 months compared to 8% for those on glatiramer acetate by the end of the 2 year study.

40.6. FDA Approved Therapies for Other Forms of MS

40.6.1. Mitoxantrone (Novantron)

Mitoxantrone (Novantron) received FDA approval for use in progressive MS in December of 2000. The recommended dosage for treatment of multiple sclerosis is 5–12 mg/mL IV every 3 months. Acute side effects of mitoxantrone include nausea and alopecia. Because of cumulative cardiotoxicity, the drug can be used for only two to three years (or for a cumulative dose of 120–140 mg per m²). A prospective study of 73 MS patients with PP MS who were followed for 10 courses of mitoxantrone (10 mg.mm² body surface) combined with methyprednisolone therapy. At mean follow up time of 23.4 months (10–57 month range), no significant changes in end-diastolic diameter, end-systolic diameter, fractional shortening was reported (Zingler et al., 2005). No evidence of signs of congestive heart failure was seen in any of the participants. However ongoing monitoring at higher cumulative doses is warranted. Mitoxantrone is a chemotherapeutic agent that should be prescribed and administered only by experienced health care professionals. A phase-III, randomized, placebo-controlled, multicenter trial found that mitoxantrone, an anthracenedione anti-neoplastic agent, reduces the number of treated MS relapses by 67%. Mitoxantrone slows progression on the EDSS, Ambulation Index, and MRI measures of disease activity (Hartung et al., 2002); it is effective and is recommended for use in patients with worsening forms of MS.

40.7. Promising Areas for a New Generation of MS Therapies

Two general areas hold the most promise in improving treatment of MS. Since all currently approved therapies require injection, the first general area involves the search for oral

therapies. The second area builds upon experience with mitoxantrone and involves testing of immunosuppressant cancer chemotherapy for use in MS.

40.7.1. Oral Therapy for MS

Preliminary studies evaluating an oral version of glatiramer acetate did not prove effective in changing the clinical outcome measures related to RR MS. Early trials of ingested IFN- α did have some biological effect (Brod et al., 1997) but have not shown the promised efficacy. Currently two other oral therapies have shown positive results in phase II clinical trials (NMMS, 2005).

The first drug, FTY20 (Novartis Pharm Corp), binds to the docking mechanism site (sphingosine-1-phosphate receptor) on immune cells including both T and B cells. The phase II clinical trial was an international double blind placebo controlled study of 281 MS patients with active RR-MS who took one of two doses of FTY20 or placebo daily for 6 months. The primary outcome measure was a change in the number of T2 enhancing lesions on monthly brain MRI. Both treatment groups had significantly fewer enhancing lesions at 6 months compared to the placebo group. The treatment groups also had fewer volume enhancing lesions and new non-enhancing lesions on MRI. Eighty six percent of those in the treatment groups remained relapse free for the 6-month study period compared to 70% for the placebo group. The most frequently reported side effects of FTY20 include mild headache, colds, and gastrointestinal disorders such as diarrhea and nausea.

The promising second oral therapy is Tamsirolimus (Wyeth Pharm). Tamsirolimus is believed to block the proliferation of immune T cells activated by interleukin, IL-2. The phase II clinical trial of Tamsirolimus was also an international double blind placebo controlled trial. The trial involved 296 patients with either RR MS or SP MS with relapses. Participants received one of three doses of oral tamsirolimus or placebo daily for 9 months. The primary outcome measure was the number of enhancing lesions after 9 months in study. By 32 weeks into the study, those in the highest treatment dose had 47.8% fewer new enhancing lesions compared to those on placebo. The high dose group also had 51% fewer relapses than the placebo group. Side effects included mouth ulceration or inflammation, menstrual dysfunction, hyperlipidemia and rashes.

40.7.2. Immunosuppressant Chemotherapies and Stem Cell Transplantation for MS

Randomized controlled trials of azathioprine, methotrexate, cladribine, intravenous immunoglobulin and cyclophosphamide have not shown definite modification to the aggressive course of PP MS (Leary and Thompson, 2005). However, these immunosuppressant therapies continue to be evaluated in patients with active aggressive MS.

Evaluation of combination therapies including cyclophosphamide show promise in decreasing the number of Gd+lesions

and slowing clinical activity in some patients where IFN β alone is not successful (Smith et al., 2005; Patti et al., 2004). A small study of 14 rapidly progressing RR MS patients given monthly IV cyclophosphamide indicates improvement in neurologic stability (Khan et al., 2001b). Further evaluation is needed to confirm the efficacy.

Autologous hematopoietic stem cell transplantation (AHSCT) was evaluated in a group of MS patients with aggressive and advanced disease (Nash et al., 2003) with some promise but also with evidence that neurologic loss continued. One important hypothesis from that study was the discordant nature of inflammatory measures and functional deficits (Healey et al., 2004).

Summary

With FDA approval of three forms of IFN β and glatiramer acetate therapy, RR MS has become a treatable disease. However, disease progression into a non-inflammatory chronic progressive disease is not effected significantly by current therapies. In addition only the immunomodulator, mitoxantrone has been approved for use in the chronic progressive form of MS. The chronic long term nature of the disease and the temporal disconnect between the identification of demyelinating CNS lesions and physical disability continue to pose problems in the development of therapies that successfully halt disability progression in MS.

Review Questions/Problems

Your brother had some “double” vision problems lately and has felt very tired. Your family physician sent him to a neurologist who scheduled several tests. On follow up, the neurologist says that your brother has optic neuritis that may potentially be associated with multiple sclerosis. The neurologist also recommends that your brother consider beginning an interferon β therapy.

- 1. What clinical data would support initiating IFN β therapy even before a definitive diagnosis of MS?**
- 2. What clinical information, in association with verification of the clinical symptoms of optic neuritis and fatigue would be sufficient to verify that the diagnosis is definitive MS using the revised MacDonald criteria?**
- 3. Your brother has received information on the two FDA approved IFN β -1a products. What are the differences in dose, dosing schedule, potential for side effects and efficacy for the two products?**
- 4. Over the next year, your brother has 2 more episodes that include problems with walking and numbness in his right hand. Are any other criteria necessary for a definitive diagnosis of MS by the revised McDonald criteria?**

5. What would you expect an MRI to show if your brother truly has MS?
6. Your brother has been on IFN β -1a IM therapy for 9 months and is still complaining of flu like symptoms and muscular aches and pain following each injection. What other therapeutic option(s) does he have?
7. How has the diagnosis of MS changed your brother's life expectancy?
8. Your brother has just had a major relapse that has left him unable to walk. What is the standard therapy for this type of acute relapse and what is the postulated mechanism of action?
9. If the previous scenario had been your sister rather than your brother, would the prognosis have been different? In either case, what is the life expectancy for them if they are in their early 30s at diagnosis?
10. Your brother continues to progress rapidly with no apparent remission even on standard immunotherapy for RR-MS. What therapy is FDA approved for rapidly progressing MS?
11. Which of the FDA approves therapies for MS was originally designed to mimic a portion of the molecular sequence of myelin:
 - a. Avonex
 - b. Betaseron
 - c. Copaxone
 - d. Rebif
12. Score for an individual with normal motor function on the Kurtzke Expanded Disability Scoring Scale (EDSS)
 - a. 0
 - b. 1
 - c. 5
 - d. 10
13. The Multiple Sclerosis Functional Composite (MSFC) does not test
 - a. motor function of the lower extremities
 - b. motor function of the upper extremities
 - c. cognitive changes
 - d. bowel and bladder function
14. The primary outcome measure for phase III FDA trials for the IFN β therapies
 - a. number and time between relapses
 - b. evidence of lesions on MRI
 - c. a significant change in the MSFC
 - d. time to complete a 25 foot walk
15. Prokarin is a trans dermal patch containing histamine and this compound
 - a. glatiramer acetate
 - b. IFN β
 - c. caffeine
 - d. corticosteroids
16. A therapy that has not shown efficacy in the treatment of MS
 - a. IFN γ
 - b. IFN β -1b
 - c. natalizunab
 - d. mitoxantrone
 - e. methyl prednisolone
17. The FDA approved therapy for relapsing remitting MS with the smallest % reduction in relapses at 12 months by the Johnson Class I data
 - a. Avonex
 - b. Betaseron
 - c. Copaxone
 - d. Rebif
18. Brain atrophy is considered significant if it exceeds the these normal changes related to aging
 - a. <0.5–1%
 - b. >0.5–1%
 - c. >1–1.5%
 - d. >5%
19. This approved therapy for relapsing remitting MS included a warning to monitor depression because of a suicide during the phase III trial.
 - a. Avonex
 - b. Betaseron
 - c. Copaxone
 - d. Rebif
20. In the Kahn head to head trial which of the following therapies was not evaluated?
 - a. Avonex
 - b. Betaseron
 - c. Copaxone
 - d. Rebif

HIV-Associated Dementia

Miguel G. Madariaga and Susan Swindells

Keywords HIV infection; dementia; antiretroviral therapy; adjuvant therapy

41.1. Introduction

This chapter reviews the use of antiretroviral therapy (ART) including its impact in altering the natural course of human immunodeficiency virus (HIV) disease; an overview of current regimens in use; factors influencing the choice of initial therapy; complications and adverse effects; and treatment failure, and resistance. The focus is on management of primary HIV-related diseases of the nervous system. While there is no specific therapy for HIV-associated dementia (HAD), both approved and developmental antiretroviral agents are discussed with a view to their effect on central nervous system (CNS) viral infection. Adverse drug effects that impact the nervous system are specifically discussed, as are pharmacological interactions between antiretroviral agents and other medications. The significance of cerebrospinal fluid (CSF) penetration by antiretroviral agents is reviewed. Adjunctive therapies, adherence to ART, treatment of comorbidities and coinfections that may worsen neurologic conditions are reviewed and include psychiatric illnesses and substance abuse. Lastly, non-pharmacological treatment strategies, education of patients and caregivers, graded assistance, behavior modification, and environment modifications are covered.

41.1.1. Overview of HIV-Related Brain Disease

Invasion of HIV into the CNS may occur early after infection, and a picture of aseptic meningitis in HIV primary infection may represent the arrival of infected macrophages. Later on, most chronically infected individuals exhibit some evidence of CNS involvement during progressive disease (Navia and Price, 2005). The target cells for HIV in the CNS are microglia and the macrophages. Once invaded, these cells express both structural and regulatory proteins and produce infectious

progeny virions. Astrocytes can also be infected in small numbers, but are only able to produce early gene proteins, and are not capable of producing infected virions (Di Stefano et al., 2005). HIV may invade the central nervous system by one or both of these proposed mechanisms:

The “Trojan Horse” model proposes that infected monocytes (but also macrophages and CD4⁺ T cells) cross the blood–brain barrier in response to chemokine stimulation. After infiltrating brain parenchyma, these cells also release additional chemokines and further attract additional inflammatory cells (Strelow et al., 2001).

Alternatively, endothelial cells and astrocytes (which compose the blood–brain barrier) are infected directly (Strelow et al., 2001). A variant of this theory is that infectious virions are transported in the cytoplasm of astrocytes and endothelial cells, and eventually transferred to central nervous system cells by transcytosis or macropynocytosis (Marechal et al., 2001).

41.1.2. Nomenclature

HAD is also referred to as HIV dementia, AIDS Dementia Complex, subacute encephalopathy, HIV encephalopathy, and HIV-1-associated cognitive-motor complex. A staging system of HAD severity was initially developed using clinical manifestations, illustrated in Table 41.1 (Price and Brew, 1988). This classification is also referred to as the Memorial Sloan-Kettering (MSK) staging system. More recently, the World Health Organization and the American Academy of Neurology developed a schema which divides the disorder into two main categories of HIV-associated minor motor cognitive disorder, and HIV-1 associated cognitive-motor complex [American Academy of Neurology (AAN), 1991].

41.1.3. Natural History of HAD

During the 1990s, several investigators identified potential risk factors for the development of HAD. These include increasing age; a history of intravenous drug use, and presence of an AIDS defining illness (Wang et al., 1995). In another cohort study, development of HAD correlated with age, lower hemoglobin,

TABLE 41.1. Clinical staging of HIV-associated dementia.

Stage	Clinical description
Stage 0 (normal)	Normal mental and motor function
Stage 0.5 (equivocal/subclinical)	Absent, minimal, or equivocal symptoms without impairment of work or capacity to perform ADL. Mild signs (snout response, slowed ocular or extremity movements) may be present. Gait and strength are normal
Stage 1 (mild)	Able to perform all but the more demanding aspects of work or ADL but with unequivocal evidence (signs or symptoms that may include performance on neuropsychological testing) of functional intellectual or motor impairment. Can walk without assistance
Stage 2 (moderate)	Able to perform basic activities of self-care but can not work or maintain the more demanding aspects of daily life. Ambulatory, but may require a single prop
Stage 3 (severe)	Major intellectual incapacity (cannot follow news or personal events, cannot sustain complex conversation, considerable slowing of all outputs) or motor disability (cannot walk unassisted, requiring walker or personal support, usually with slowing and clumsiness of arms as well)
Stage 4 (end stage)	Nearly vegetative. Intellectual and social comprehension and output are at a rudimentary level. Nearly or absolutely mute. Paraparetic or paraplegic with urinary and fecal incontinence

Source: Adapted from Price and Brew (1988).

lower body mass index and more constitutional symptoms (McArthur et al., 1993). Psychomotor slowing, a history of HIV related disease, extrapyramidal symptoms, depression and elevated serum beta 2 microglobulin levels have also been shown to be associated with development of dementia (Stern et al., 2001). Other risk factors include CD4⁺ T cell nadir, the zenith of viral load, and duration of HIV disease (Childs et al., 1999). Individuals with plasma HIV RNA of more than 30,000 copies/mL at baseline had 8.5 times higher chance of developing dementia as compared with those with less than 3,000 copies/mL. Similarly, patients with CD4⁺ T cell counts below 200 cells/mm³ had 3.5 more chance of developing dementia as compared with those with CD4 counts of higher than 500 cells/mm³. Finally, additional risk factors for HIV dementia may incorporate a number of genetic factors such as the presence of ApoE4 genes, MCP-1 mutations, mutations in the CCR2 receptor, and TNF receptor polymorphisms.

Initial estimates on the prevalence of HAD were as high as 66%, but more recently reported at 7% (Navia and Price, 1987; Janssen et al., 1992). With the widespread use of potent, combination ART, the overall incidence of HAD has decreased dramatically. For example, the incidence of newly diagnosed moderate-to-severe dementia fell from 6.6% in 1989, to 1% in 2000 (McArthur et al., 2003). In addition, the mean CD4⁺ T cell count for patients with HAD has progressively increased with access to improved ART. A study by the National Centre in HIV Epidemiology and Clinical Research at the University

of New South Wales demonstrated that the median CD4⁺ T cell count at diagnosis of HAD increased from 70 cells/mm³ in 1992–1995, to 120 cells/mm³ in 1996, and to 170/mm³ in 1997 ($P = 0.04$) (Dore et al., 1999). These data suggest that ART may have a lesser impact on the incidence of HAD than on other AIDS-defining conditions, and some investigators speculate that poor CNS penetration of many antiretroviral agents is a possible explanation.

Not only is the CD4⁺ T cell count higher, but also the mean time from diagnosis of HIV dementia to death has extended from 6 months to 44 months, and the clinical presentation has changed with more “cortical” manifestations as compared with previously reported “subcortical” presentations (Brew, 2004). HAD appears to be more stable of late, and does not progress as rapidly (McArthur et al., 2003). Some patients may have residual neurological deficits which are irreversible and do not improve with additional ART (Saksena and Smit, 2005).

41.2. Diagnosis

41.2.1. Clinical Findings

In the early stages of HAD, the most common findings are cognitive difficulties, particularly deficits in attention and concentration. Initial changes may be subtle: losing one's train of thought, requiring lists to remember chores, or inability to perform multitask tasks. In more advanced stages, cognitive impairment is more obvious. Patients are unable to perform complex tasks, lose the ability to read, language skills deteriorate, thought processes are generally slower. Mood changes include increasing irritability and apathy, and later on, frank disorientation may develop.

Motor symptoms are less common, but loss of fine motor movements frequently develops; for example, the dexterity required for playing a musical instrument, or doing and undoing buttons. Tremor and myoclonus are rare. Gait may become hesitant and slow, and patients may lose balance. Deep tendon reflexes in the lower extremities become brisk, and occasionally a Babinski sign or other pyramidal release sign may be observed.

41.2.2. Diagnostic Studies

41.2.2.1. Neuropsychological Testing

Neuropsychological testing in HIV dementia is a useful tool for the differential diagnosis of HAD and to delineate disease extension and progression. The standard Mini-Mental Status is not particularly sensitive for detection of early HAD, however patients may fail in reversing a five-letter word or subtracting from 100 by 7's, and may fail in complex sequential tasks, or remembering three objects. Important information can be obtained by patient self-report and by guided interviews, as well as by behavioral observation. More formal neuropsychological testing is the standard of care, if available. Extended neuropsychological batteries can be used in clinical practice, but are time consuming especially in a busy clinical setting.

TABLE 41.2. Common neuropsychological batteries for HAD.

Organization	Tests included
National Institute of Mental Health (NIMH) Workgroup	WAIS-R Vocabulary WMS-R Visual Span Paced Auditory Serial Addition Test California Verbal Learning Test Hamilton Depression Scale Spielberger State-Trait Anxiety Scale San Diego HIV Neurobehavioral Research Center (HNRC) Paced Auditory Serial Addition Test
San Diego HIV Neurobehavioral Research Center (HNRC)	Boston Naming Test Thurstone Written Fluency Story Learning and Memory Figure Learning and Memory Finger Tapping Test Grooved Pegboard Test WAIS-R Digit Span
Multicenter AIDS Cohort Study (MACS)	Controlled Oral Word Association Test Rey Auditory Verbal Learning Test Trail Making Test Symbol Digit Modalities Test Grooved Pegboard Test CES Depression Scale

More focused neuropsychological batteries have been developed for this purpose, such as those listed in Table 41.2. The HIV Dementia Scale is also a useful tool and only takes five minutes to administer and score (Power et al., 1995). It is important to remember that interpretation of neuropsychological tests also requires attention to patient demographics such as language skills, presence of comorbid conditions, substance abuse, and concomitant use of psychotropic medications.

41.2.2.2. Neuroimaging and Evoked Potentials

Imaging studies in HAD may include structural brain imaging such as brain magnetic resonance imaging (MRI) and functional or metabolic imaging. Previous cross sectional studies have shown that HIV-infected individuals tend to have generalized brain atrophy, which may be more prominent in individuals with HAD (Aylward et al., 1993, 1995). Particularly, there is gray matter volume reduction in the basal ganglia and posterior cortex, as well as generalized volume reduction of white matter. These findings are consistent with the characterization of HAD as a subcortical dementia. Studies using diffusion tensor imaging (DTI), a magnetic resonance imaging technique suited for the study of subtle white matter abnormalities, have found abnormal fractional anisotropy in the white matter of the frontal lobes and internal capsules of HIV-infected patients (Pomara et al., 2001). This method may be more sensitive than conventional MRI methods for detecting subtle white matter disruptions. Longitudinal studies have shown that with progression of dementia, white matter volume progressively declines and consequently the volume of ventricular CSF increases (Stout et al., 1998). Also, the caudate nucleus sustains accelerated volume loss. All these changes may regress, at least in part, with initiation of potent ART (Filippi et al., 1998).

Several types of functional imaging have been used in HAD including use of positron emission tomography (PET) and single-photon emission computed tomography (SPECT); however the most promising imaging seems to be magnetic resonance spectroscopy. Studies performed using this method showed mild increase in myoinositol and choline-containing compounds in white matter, which correlates with glial damage (McConnell et al., 1994). In more advanced disease states, the increase is marked and also associated with reduction *N*-acetyl aspartate, which is a marker of neuronal loss. These changes may also be reversible with ART. Several studies, but not all, have also found evidence of delayed endogenous event-related potentials in patients with HIV infection (Clifford, 2002b). The delay becomes more prominent in the presence of dementia, and delayed potentials may even precede clinical disease. More recently it has been observed that the classical abnormalities seen on brain imaging in the basal ganglia are now less conspicuous, and mesial temporal lobe abnormalities seem to be more prominent both by PET scanning and on histopathology (Brew, 2004).

41.2.2.3. CSF Studies

While HAD is a diagnosis of exclusion without pathognomic findings in CSF, HIV does elicit an inflammatory response that can be detected. This may manifest as mild lymphocytic pleocytosis, elevation of total protein, increase of total IgG, and/or the presence of oligoclonal bands. In addition, elevation of CSF levels of neopterin, beta 2 microglobulin, quinolinic acid, metalloproteinases and several other cytokines (IL-1, IL-6, TNF- α), and chemokines such as monocyte chemoattractant protein 1, and IP-10 has been reported (Anderson et al., 2002; Gendelman and Persidsky, 2005). However, correlation of such markers with clinical disease is controversial (Brew, 2004). To complicate matters, ART may suppress markers of inflammation, but the degree of reduction attained by different drugs is variable and the suppression may not be durable (Gendelman et al., 1998). Measurement of virus load in the CSF using polymerase chain reaction (PCR) or other technologies has also produced contradictory findings. In contrast to plasma virus load which correlates well with severity of HIV disease and response to therapy, finding of a positive virus load in the CSF does not necessarily correlate with the diagnosis of HAD and may be present in asymptomatic individuals (Price et al., 2001). Also, viral replication may be inhibited in the periphery but not in the CSF, and neuroinflammation may return despite initial effective therapy (Letendre, 2005).

41.2.2.4. Histopathology

The pathological substratum of HIV dementia is referred to as HIV encephalitis (HIVE). HIVE is a disseminated multifocal process characterized by the presence of multinucleated giant cells of macrophage/microglial origin; microglial nodules; diffuse astrogliosis; myelin pallor; loss of synaptic density; and neuronal cell loss, mainly in the hippocampus,

basal ganglia and orbitofrontal cortex, usually sparing of the occipital cortex (Budka, 2005). Necrotic areas may be present. On rare occasions, inflammatory changes may affect the meninges and ventricles causing HIV meningoventriculoencephalitis. Less common subtypes of histopathology include HIV demyelinating leukoencephalopathy, which can be seen in patients failing ART, and is characterized by diffuse damage of white matter, lacking prominent signs of inflammation. HIV vacuolar leukoencephalopathy has histopathology similar to HIV vacuolar myelopathy, and granulomatous angiitis is another less common manifestation.

41.3. Antiretroviral Therapy

The introduction of potent, combination ART and the use of prophylactic medications against opportunistic infections had a significant impact on the natural history of HIV (Palella et al., 1998). Morbidity and mortality have declined dramatically, and HIV has evolved from a fatal disease to a chronic, manageable condition. Immune reconstitution achieved with ART can be potent and sustained enough that primary and secondary prophylaxis against opportunistic infections can be safely discontinued (www.aidsinfo.nih.gov).

Antiretroviral agents currently in use include inhibitors of reverse transcriptase, HIV protease, and fusion inhibitors. Several other compounds are in development including

chemokine receptors inhibitors, viral integrase inhibitors, inhibitors of HIV regulatory genes and their byproducts, and inhibitors of viral budding.

41.3.1. Antiretroviral Classes

Currently, there are four classes of antiretroviral agents available in the United States for clinical use:

Nucleoside analogue reverse transcriptase inhibitors (NRTIs),
Nonnucleoside analogue reverse transcriptase inhibitors (NNRTIs),
Protease inhibitors (PIs),
Entry inhibitors.

NRTIs are phosphorylated and converted into triphosphate forms by nucleoside kinases. These activated forms have high levels of affinity for HIV-1 reverse transcriptase and compete with the natural deoxynucleoside triphosphates. Once incorporated into the growing chain of DNA, lack of a 3'-hydroxyl group that can form a phosphodiester bond with the incoming nucleoside causes chain termination. Tenofovir is an exception in this group as it is a nucleotide analogue rather than nucleoside and, as such, requires only two phosphorylation steps instead of three to become the active form. Pharmacological characteristics of FDA approved NRTIs are presented in Table 41.3.

NNRTIs are drugs of diverse chemical structure that act by non-competitive inhibition of HIV-1 reverse transcriptase. They do not require intracellular phosphorylation to be activated. NNRTIs inhibit the enzyme allosterically by binding

TABLE 41.3. Selected characteristics of nucleoside reverse transcriptase inhibitors.

Generic/trade name (abbreviation)	How supplied	Usual adult dose	Major adverse effects	Ratio of CSF level to IC ₅₀ ^a
Abacavir/Ziagen (ABC)	300 mg tablets	300 mg b.i.d. or 600 mg once daily	Hypersensitivity reaction, which can be fatal	4.0
Didanosine/Videx EC (ddI)	125, 200, 250, or 400 mg enteric-coated capsules	Body weight >60 kg: 400 mg once daily; <60 kg: 250 mg once daily	Peripheral neuropathy, pancreatitis, lactic acidosis with hepatic steatosis	0.11
Emtricitabine/Emtriva (FTC)	200 mg capsules	200 mg q.d.		—
Lamivudine/EpiVir (3TC)	150 and 300 mg tablets	150 mg b.i.d. or 300 mg once daily		0.74
Stavudine/Zerit (d4T)	15, 20, 30, or 40 mg capsules	>60 kg: 40 mg b.i.d.; <60 kg: 30 mg b.i.d.	Peripheral neuropathy, pancreatitis, lactic acidosis with hepatic steatosis, neuromuscular weakness (rare)	0.58
Tenofovir/Viread (TDF)	300 mg tablets	300 mg q.d.	GI intolerance, renal insufficiency (rare)	—
Zalcitabine/Hivid (ddC) ^b	0.375 or 0.75 mg tablets	0.75 mg t.i.d.	Peripheral neuropathy, lactic acidosis with hepatic steatosis	0.08
Zidovudine/Retrovir (AZT, ZDV)	100 mg capsules, 300 mg tablets	200 mg t.i.d. or 300 mg b.i.d.	Bone marrow suppression	0.6

^a The ratio between pharmacokinetic measures, such as the plasma minimum concentration (C_{min}), and the 50% inhibitory concentration (IC₅₀) provides a measure of systemic antiviral efficacy. Similarly, the ratio of CSF concentrations to IC₅₀ may provide a better estimate of CNS efficacy than CSF concentration alone.

^b Anticipate discontinuation of distribution in 2006.

Note: Several fixed dose NRTI combination tablets are also available:

- Abacavir 600 mg + lamivudine 300 mg as Epzicom
- Emtricitabine 200 mg + tenofovir 300 mg as Truvada
- Lamivudine 150 mg + zidovudine 300 mg as Combivir
- Abacavir 300 mg + lamivudine 150 mg + zidovudine 300 mg as Trizivir
- Emtricitabine 200 mg + tenofovir 300 mg + efavirenz 600 mg as Atripla

to a hydrophobic pocket in the p66 subunit of reverse transcriptase, which is close to the catalytic site of the enzyme. Several pharmacological properties of NNRTIs are presented in Table 41.4.

PIs act by impeding the action of the HIV-1 protease, an aspartic protease that cleaves the gag and gag-pol precursor molecules into smaller structural proteins and enzymes. By doing this, PIs prevent viral maturation and produce defective viral particles without an electrodense core, and these are unable to infect new cells. Several pharmacological properties of PIs are presented in Table 41.5.

The first entry inhibitor to be licensed in the United States was enfuvirtide. A synthetic peptide, this compound has the ability to inhibit fusion of virions to the host cells by preventing the conformational change of gp41. The peptide

is not bioavailable when taken orally and requires subcutaneous administration. The drug is generally well tolerated although can be associated with local reactions at the site of injection. Clinical benefit has mostly been demonstrated in heavily experienced patients with multidrug resistant virus (Trottier et al., 2005). The impact of enfuvirtide on HAD is not known.

41.3.2. Initiating Antiretroviral Therapy: When and What to Start

Recent guidelines for starting of ART recommend that patients with advanced disease, as manifested by the development of an AIDS-defining illness including HAD, or presence of severe symptoms such as unexplained fever, persistent diarrhea, or unexplained weight loss, should be started on ART regardless of their CD4⁺ T cell count (www.aidsinfo.nih.gov). Asymptomatic patients with CD4⁺ T cell counts below 200 cells/mm³ should also be treated. Asymptomatic patients with CD4⁺ T cell counts between 200–350 cells/mm³, may be offered treatment at the discretion of the treating clinician and in collaboration with the patient. In patients with CD4⁺ T cell counts above 350 cells/mm³, the majority of clinicians would recommend deferring therapy. Some clinicians will treat if patients have a viral load of more than 100,000 copies/mL. Indications for starting of ART are summarized in Table 41.6.

Based on data from clinical trials, either an NNRTI-based or PI-based regimen should be offered to antiretroviral-naïve patients for whom therapy is indicated. The preferred NNRTI-based regimen includes efavirenz and two NNRTIs; either lamivudine or emtricitabine plus zidovudine or tenofovir.

TABLE 41.4 Selected characteristics of non-nucleoside reverse transcriptase inhibitors.

Generic/trade name (abbreviation)	How supplied	Usual adult dose	Major adverse effects	CSF/IC ₅₀
Delavirdine/Rescriptor (DLV)	100 or 200mg tablets	400 mg t.i.d.	Rash, increased transaminases	186
Efavirenz/Sustiva (EFV)	50, 100, or 200mg capsules or 600mg tablets	600 mg q.h.s.	Neuropsychiatric manifestations, rash, increased transaminases	5.7
Nevirapine/Viramune (NVP)	200mg tablets	200mg q.d. for 14 days then 200mg b.i.d.	Rash, hepatitis	241

TABLE 41.5. Selected characteristics of protease inhibitors.

Generic/trade name (abbreviation)	How supplied	Usual adult dose	Major adverse effects	CSF/IC ₅₀
Atazanavir/Reyataz (ATV)	100, 150, or 200mg capsules	400 mg q.d. or 300 mg q.d. with ritonavir when used with TDF or EFV	Hyperbilirubinemia, atrio-ventricular block	0.02
Fosamprenavir/Lexiva (f-APV)	700mg tablets	700 mg b.i.d. or 1400 mg q.d. with ritonavir	GI intolerance, rash	–
Indinavir/Crixivan (IDV)	200, 333, or 400mg capsules	800mg q. 8 h or 800mg b.i.d. with ritonavir	Nephrolithiasis, GI intolerance, hyperbilirubinemia, metabolic complications	108
Nelfinavir/Viracept (NFV)	250mg tablets	750 mg t.i.d. or 1250 mg b.i.d.	Diarrhea, metabolic complications	4.3
Ritonavir/Norvir (RTV)	100mg capsules	600 mg q. 12 h (rarely used)	GI intolerance, hepatitis, pancreatitis, metabolic complications	3.3
Saquinavir/Fortovase ^a (SQV-sgc)	200mg soft gel capsules	1200 mg t.i.d.	GI intolerance, increased transaminases, metabolic complications	4.0
Saquinavir/Invirase (SQV)	200mg capsules	1,000 mg b.i.d. with 100 mg bid of ritonavir; invirase alone is not recommended	GI intolerance, increased transaminases, metabolic complications	4.0
Tipranavir/Aptivus (TPV)	250mg capsules	500 mg b.i.d. with ritonavir 200 mg bid	GI intolerance, increased transaminases, metabolic complications	–
Lopinavir 133.3 mg + ritonavir 33.3 mg/Kaletra (LPV/r)	Fixed combination capsules	3 capsules b.i.d.; 4 capsules bid with EFV or NVP	GI intolerance, increased transaminases, metabolic complications	3.3
Darunavir/Prezista (DRV)	300mg capsules	2 capsules b.i.d. with ritonavir 100 mg b.i.d.	GI intolerance, rash	–

^a Distribution of Fortovase is anticipated to discontinue in 2006.

TABLE 41.6. Guidelines for the initiation of antiretroviral therapy.

Clinical category	CD4 ⁺ T cell count	Plasma HIV RNA level	Recommendation
AIDS-defining illness or severe symptoms	Any value	Any value	Treat
Asymptomatic	CD4 ⁺ T cells <200/mm ³	Any value	Treat
Asymptomatic	CD4 ⁺ T cells 200–350/mm ³	Any value	Treatment should be offered following full discussion of pros and cons with the patient
Asymptomatic	CD4 ⁺ T cells >350/mm ³	>100,000 copies/mL	Most clinicians recommend deferring therapy, but some would treat
Asymptomatic	CD4 ⁺ T cells >350/mm ³	<100,000 copies/mL	Defer therapy

However, other NRTIs may be used as a backbone including stavudine, didanosine and abacavir, and nevirapine can be substituted for efavirenz. Important exceptions to NRTI combinations include zidovudine with stavudine (competitive enzyme antagonism), zalcitabine with didanosine (increased risk of mitochondrial damage and peripheral neuropathy), stavudine with didanosine (increased risk of pancreatitis and lactic acidosis, especially in pregnant women), zalcitabine with lamivudine (competitive inhibition of intracellular phosphorylation), and didanosine with tenofovir (high rate of early virological failure). Because of teratogenicity in animals, efavirenz should not be used in pregnant women or those with high risk of pregnancy.

Preferred PI-based regimens are lopinavir/ritonavir plus lamivudine or emtricitabine plus another NRTI, usually zidovudine, stavudine or abacavir. Alternative combinations include other PIs with or without ritonavir, and two NRTIs. The combination of a protease inhibitor with ritonavir provides inhibition of cytochrome p450 enzymes and permits less frequent dosing of amprenavir, indinavir, lopinavir and saquinavir. Use of ritonavir in this setting is also known as “boosting.”

Abacavir plus lamivudine plus zidovudine, which is commercially available as a fixed combination in a single tablet, has inferior rates of viral suppression and should only be used when an NNRTI or a PI-based regimen cannot or should not be used as first line of therapy (Gulick et al., 2004).

41.3.3. Antiretroviral Treatment Failure

Despite major advances in treatment of progressive HIV disease, approximately 40% of patients will not achieve sustained viremia below the limits of detection, which is the accepted definition of treatment success (Lucas et al., 1999).

Poor adherence is the most important cause of failure of ART, and cognitive impairment is clearly a risk factor for this, such as in patients with HAD. Other reasons include drug intolerance, development of adverse effects, impaired drug absorption and/or metabolism, pharmacokinetic interactions, and pre-existing viral resistance.

The development of viral drug resistance, particularly in patients with poor adherence, is a major concern in clinical practice. A listing of drug resistance mutations in HIV-1 is continuously updated and available from the International AIDS Society-USA at http://www.iasusa.org/resistance_mutations/index.html. If viral resistance is suspected, testing for mutations is helpful in choosing subsequent regimens and has been shown to improve biological outcomes. Both genotyping and phenotyping assays are commercially available, and there are no data to support the utility of one method over the other; although, genotyping is usually less expensive and the results may be available faster.

41.3.4. Importance of CNS Penetration in the Treatment of HAD

With regard to HIV disease, the CNS is both a biological and a pharmacological compartment. It is considered a biological compartment because HIV can replicate independently from virus in the periphery. It is also considered a pharmacological compartment because the blood–brain barrier acts as an obstacle to the penetration of antiretroviral drugs, many of which are highly plasma-protein bound. Both facts may predispose to the development of antiretroviral resistance in CNS, independently from that in plasma. This phenomenon has been observed in patients failing therapy (Cunningham et al., 2000). Hence, the penetration of drugs into the CNS has potential clinical relevance.

Penetration of antiretroviral drugs into the CNS depends on many factors. Protein binding is particularly important because only free drug is able to diffuse across the blood–brain barrier. Other factors that help with penetration into the CNS include small molecular size, a higher degree of acidity; higher lipophilicity; and the presence of inflammation, which may favor the accumulation of drugs in the CNS. The CSF level of an antiretroviral agent is used as a surrogate for drug penetration into the brain parenchyma, although this is not necessarily the optimal approach.

Because it has been assumed that drugs with better CSF penetration would be more effective in treating HAD, particular attention has been paid to antiretroviral agents with higher CSF:plasma concentrations. Among the NRTIs, zidovudine has been widely studied and is known to cross the blood–brain barrier well by passive diffusion. Dideoxyinosine (ddI) and dideoxycytidine (ddC) have poor uptake in the CNS, probably due to their hydrophilic composition. Lamivudine (3TC) has a structural composition similar to ddC and its degree of absorption and efflux are probably similar as well. Stavudine (d4T) may have good penetration into the CSF. Data concerning CSF

penetration of licensed antiretroviral agents are included in Tables 41.3, 41.4, and 41.5.

Among the NNRTIs, nevirapine has the highest penetration. Protease inhibitors have poor penetration because they are highly protein bound in plasma. Despite this fact, protease inhibitors have been successful in the treatment of HAD (Gendelman et al., 1998; Saksena and Smit, 2005). Some investigators believe that control of virus replication in the periphery may be sufficient to reverse HIV-related brain disease. Improvement in immune status from ART may also reconstitute the defective blood–brain barrier, which is seen in later stages of HIV infection (Evers et al., 2004). The importance of CNS penetration in the treatment of HAD is therefore controversial, and drugs which do not have adequate CSF levels may still be effective.

Although viral decay in CSF usually parallels that in plasma, occasionally there can be variability and may even be increases of RNA in the CSF despite a decline in plasma levels. These differences in the decay kinetics may be related to the type of cells infected in each compartment: CD4⁺ T cells in plasma, which are rapidly destroyed, versus monocytes and macrophages in the brain, which persist longer (Eggers et al., 2003).

41.3.5. Role of Specific Antiretroviral Agents in the Treatment of HAD

Zidovudine monotherapy was the only available treatment for HIV disease before the 1990s, and was used until 1992. Zidovudine monotherapy has been proven to be efficacious for both the treatment of HAD as well as for HIV-associated minor cognitive/motor disorder (MCMD) (Arendt et al., 1992; Sidtis et al., 1993; Tozzi et al., 1993). Unfortunately, the beneficial effect of zidovudine was transient and an addition of a second NRTI such as dideoxyinosine (ddI), lamivudine (3TC), or dideoxycytidine (ddC), may not further improve psychomotor performance. Stavudine was shown to improve motor performance even after pretreatment with zidovudine (Arendt et al., 2001). A study in 1998, using abacavir versus placebo showed no neurologic deterioration in the abacavir group as compared with the placebo group (Lanier et al., 2001). However, there was no benefit when abacavir was added to a stable ART, despite good proven CNS penetration.

Among the NNRTIs, nevirapine has the best penetration in the CSF with a CSF to plasma ratio up to 40%. Efavirenz is highly protein-bound and has a much lower CSF:plasma ratio, however drug levels in the CSF have been able to successfully inhibit HIV infection in microglia in vitro (Albright et al., 2000). Both NNRTIs have been shown to improve HIV-associated MCMD in both naïve and antiretroviral-experienced patients (Arendt and von Giesen, 2002). There are no data available about the use of delavirdine in HAD.

Protease inhibitors are highly protein-bound. The PIs studied in the CSF include saquinavir, indinavir, and nelfinavir. All of them have very low CSF: plasma ratios. However, several

studies have shown some improvement in psychomotor slowing in patients treated with a combination of ART including a PI (Gendelman et al., 1998; Sacktor et al., 1999).

41.4. Adverse Neurologic Effects of Antiretroviral Agents

A detailed reviewed of the toxicity of all antiretrovirals is beyond the scope of this chapter, but information about adverse effects of each drug are available in the package inserts. Commonly occurring neurological toxicities are outlined in the following paragraphs. Management of adverse events from antiretroviral agents typically involves substitution of the offending agent, ideally with a drug from the same class but with a different toxicity profile. Dose modification may be needed to correct for drug interactions when used in certain combinations with NNRTIs and/or PIs.

Distal sensory peripheral neuropathy (DSPN) has been associated with the use of ddC, ddI, and stavudine, alone or in combination. The symptoms of this condition include a burning sensation in feet and hands, numbness and tingling in the feet, cramps in the legs, and absent ankle reflexes. The patient may also exhibit decreased sensation to temperature, pinprick, vibration, and proprioception (Dieterich, 2003). The symptoms are similar to HIV associated axonal neuropathy. This condition may become irreversible, so it is important to diagnose it earlier. The treatment of choice is symptomatic therapy and discontinuation of the toxic agent when possible.

Myopathy mainly affecting the proximal lower limb muscles has been associated with use of zidovudine in up to 18% of cases. The cases have usually occurred after the use of zidovudine for several months. The manifestations of this condition include: myalgias, elevation of creatine kinase, and muscle biopsy revealing ragged root fibers. Zidovudine induced-myopathy may be difficult to distinguish from HIV-associated myopathy. The management may include close monitoring, but in patients who have more severe symptoms, discontinuation of zidovudine may be necessary. A short course of anti-inflammatory drugs or corticosteroids, or even intravenous immunoglobulin has been advocated but has not been evaluated in controlled clinical trials. Zidovudine may also cause headaches in up to 50% of cases. The headache induced by zidovudine can be so severe that it may motivate stopping the medication (Enzensberger and von Giesen, 1999).

There have been reports of HIV-associated neuromuscular weakness, probably associated with symptomatic lactic acidosis (Estanislao et al., 2004). Lethal cases have been reported in association with stavudine. Usually the cases have occurred after several months of use of the medication and have been associated with sensory motor neuropathy and elevated serum lactate levels. It is tempting to include this condition as another manifestation of mitochondrial damage induced by NRTIs.

Central nervous toxicity has been seen with efavirenz (Clifford et al., 2005). Manifestations of this process include

headache, dizziness, confusion, agitation, amnesia, hallucinations, insomnia, and abnormal vivid dreams. These symptoms occur usually within the first four weeks of treatment, and decline afterwards with time. Dosing the medication at bedtime makes the symptoms more tolerable. Education of the patient about the potential adverse effects of the drug is important to prevent treatment interruptions. Efavirenz may also be associated with depression, anxiety, and suicidal ideation and patients with a history of mental disorders may need to be monitored closely when started on efavirenz. There are no specific therapies for the side effects except discontinuation of the medication if the symptoms are severe enough (Treisman and Kaplin, 2002).

Protease inhibitors are not particularly associated with neurologic side effects but because they tend to cause inhibition of the P450 enzymes, they may alter the metabolism of neurotropic drugs and as a consequence may precipitate neurologic effects (Treisman and Kaplin, 2002).

41.4.1. Pharmacological Interactions Between Antiretrovirals and Other Medications with Activity in the Central Nervous System

The American Psychiatry Association emphasizes that when using psychoactive medications in HIV infected patients, several measures should be considered, such as using lower starting doses and a slow titration, providing simple dosing skills, maintaining awareness of potential drug-drug interactions and of possible adverse effects (http://www.psych.org/psych_pract/treatg/pg/hivavids_revisebook_index.cfm). In particular, PIs and NNRTIs inhibit or induce cytochrome p450, which shares the same metabolic pathway with many psychotropic agents. Among PIs, ritonavir is the most powerful inhibitor, saquinavir being the weakest, and other ones being intermediate. In general, by inhibiting the cytochrome p450 isoenzyme, plasma levels of psychotropic medications are increased. Concomitant use of selective serotonin reuptake inhibitors (SSRIs) and PIs may cause serotonin syndrome (Gillenwater and McDaniel, 2001). Tricyclic antidepressants in higher concentrations may cause delay cardiac conduction, anticholinergic effects and orthostasis. Newer antidepressants such as nefazodone may cause adverse effects if coadministered with ritonavir. The same applies for pimozide, an antipsychotic that may be associated with cardiac arrhythmia; and with benzodiazepines, which can be associated with respiratory depression. Clozapine can also be associated with seizures. In addition, antipsychotics can be associated with extrapyramidal side effects, including severe dystonia, akathisia, and Parkinsonism.

Sodium valproate is used as a mood stabilizer but has also been shown inhibit an enzyme associated with maintenance of HIV latency (Lehrman et al., 2005). Levels of valproate may be increased by concomitant use of zidovudine. Lithium should be used with caution, especially in patients who have some degree of nephropathy. Carbamazepine is also known to induce

activity of the cytochrome p450, and has the potential for bone marrow toxicity, so it is rarely used in HIV-infected patients.

Many recreational drugs such as benzodiazepines, amphetamines, and opioids are also metabolized by the liver. Although information is scant about the clinical significance and interactions between these drugs and antiretroviral agents, unintentional overdoses with methamphetamine and gamma hydroxybutyrate have been reported in patients using PIs, particularly ritonavir. PIs and NRTIs may alter metabolism of methadone and precipitate opioid withdrawal (McCance-Katz et al., 2003).

41.5. Adjuvant Pharmacological Therapy for HAD

Several drugs have been tested as adjunctive agents for the therapy of HAD. This section mainly describes medications that have been subject to clinical trials, with a brief description of other potentially promising compounds.

41.5.1. CPI/1189

CPI/1189 is a lipophilic antioxidant with the chemical structure of a synthetic benzamide, which may have some anti-tumor necrosis alpha activity by scavenging superoxide anion radicals. Tumor necrosis alpha is a critical factor in the pathology of neurologic dysfunction, and has been shown to be associated with HIV encephalitis. CPI/1189 was tested in a clinical trial of 64 patients with HAD. The drug caused improved performance on the Grooved Pegboard Tests, a test for psychomotor speed, but no effect in the composite scores for eight other neuropsychological measures. In addition, although relatively well tolerated, CPI/1189 was associated with some serious adverse effects including: elevation of liver enzymes, possible cataract formation, and decrease in the mean corpuscular volume (Clifford et al., 2002a).

41.5.2. Lexipafant

Neuronal death can be caused by inflammatory mediators including lipid membrane derivatives such as platelet activating factor (PAF). PAF itself may be neurotoxic by increasing the release of glutamate and calcium. Lexipafant is a PAF inhibitor and was studied in a randomized double-blind placebo-controlled trial involving 30 HIV-infected individuals with cognitive impairment (Schifitto et al., 1999). The drug was well tolerated, but there were no significant differences between the placebo and the treatment groups on neuropsychological function.

41.5.3. Memantine

Memantine is a competitive inhibitor of the *N*-methyl-D-aspartate glutamate receptor (NMDA). Clinically, memantine has been effective in the treatment of Alzheimer's dementia and

was thought to show promise for the treatment of HAD. A large, double-blind, placebo-controlled trial was designed in the late 1990's (AIDS Clinical Trials Group protocol 301) and showed a trend towards improvement in some neuropsychological testing; but no significant, sustained improvement. (Schifito et al., 2007a).

41.5.4. Minocycline

Minocycline is a long acting tetracycline derivative and has recently been shown to have neuroprotective effects in an animal model of simian immunodeficiency virus (SIV) encephalitis (Zink et al., 2005). The drug crosses the blood barrier and has anti-inflammatory properties by suppressing the p38 mitogen-activated protein kinase. In a small study, comparing minocycline-treated and untreated macaques exposed to SIV, the treated macaques had less severe encephalitis, reduced CNS expression of neuroinflammatory markers (such as major histocompatibility complex class II, macrophage marker CD68, T-cell intracytoplasmic antigen 1, CSF monocyte chemoattractant protein 1), reduced activation of p38 mitogen-activated protein kinase, less axonal degeneration, and lower CNS virus replication. The study also showed that minocycline was able to inhibit SIV and HIV in vitro, probably not by direct antiviral effect but by rendering the intra- or extra-cellular environment hostile for viral proliferation. Another experiment using microglial cultures corroborated that minocycline inhibits HIV production by interrupting nuclear factor NF-kappa B activation and HIV-1 long terminal repeat (LTR)-promoter activity in U38 cells (Si et al., 2004). Clinical trials in humans are in development.

41.5.5. Nimodipine

Glycoprotein 120 (gp120) causes injury in rodent retinal ganglion cells and hippocampal neurons in culture, as a consequence of increased intracellular calcium. The addition of the calcium channel blocker, nimodipine, decreases the levels of intracellular calcium and has been shown to prevent neuronal damage (Dreyer et al., 1990). Similarly, the cytotoxic effect of gp120 was monitored in a population of human neurons. The use of different doses of gp120 was associated with up to 27% loss of viable cells. Nimodipine was able to prevent this cytotoxic effect, presumably by blocking the *N*-methyl-D-aspartate (NMDA) receptor channels, which allow calcium ions to enter the cell (Wu et al., 1996). It has also been suggested that the HIV tat protein may activate a sensitive calcium influx pathway in microglial cells (Contreras et al., 2005).

To date, one clinical trial has evaluated the role of nimodipine in the treatment of HAD. A multicenter phase I/II study by the AIDS Clinical Trial Group enrolled 41 patients with different degrees of HAD (Navia et al., 1998). Patients were assigned to one of three arms: placebo, nimodipine 30 mg orally tid or nimodipine 50 mg five times a day for 16 weeks. Patients in all arms received an NRTI (zidovudine, didanosine

or zalcitabine). An intent-to-treat analysis showed no significant difference in the neuropsychological Z score (NPZ-8), a composite for eight neuropsychological tests or in the CSF levels of neopterin or beta-2 microglobulin. There was, however, a nonsignificant improvement in the arm with the highest dose of nimodipine. There was no difference in the toxicity caused by placebo or nimodipine.

41.5.6. OPC-14117

OPC-14117 is a lipophilic compound with a chemical structure similar to vitamin E. The compound is a scavenger of superoxide anion radicals, which may be implicated in the pathogenesis of HAD. In fact, it has been proposed that oxidative stress and excessive activation of glutamate receptors may represent a sequential pathway for cell vulnerability in the brain. Based on this, a double-blind, placebo-controlled, randomized clinical trial was organized by the Charles A. Dana Foundation Consortium on the Therapy of HIV Dementia and Related Cognitive Disorders (The Dana Consortium, 1997). Thirty individuals with HIV infection and evidence of cognitive impairment, and who were taking a stable antiretroviral regimen for six weeks prior to randomization, were randomized to receive tablets of OPC-14117 or placebo. The primary outcome measure was safety of the drug including ability of the subjects to complete the study and frequency of adverse effects.

There was no reported differences in tolerability between the treatment groups. The adverse experiences reported to be of severe intensity included metabolic encephalopathy, parotid tumor, diarrhea, fatigue, pneumonia, and nausea and all occurred in the placebo-treated group. In the treated group there was asymptomatic elevation of liver enzymes which required halving the dose of the medication. After 12 weeks of follow up, there was a trend towards improvement in the Rey Auditory Verbal Learning Recall, Delayed Recall Subscales, and in the timed gait test, favoring the OPC group, however the differences were not significant. There were no significant differences between the groups on mean changes in function, mood, CD4 lymphocyte count, and beta-2-microglobulin levels. So, although safe, the medication did not produce significant clinical improvement.

41.5.7. Peptide T

Peptide T or d-ala-peptide-d-amide is an octapeptide (Ala-Ser-Thr-Thr-Thr-Asn-Tyr-Thr), which is so named because of the many threonine aminoacids included in its sequence. This peptide is involved in the attachment sequence of the gp120 molecule of HIV to the CD4 receptor (Ruff et al., 1987). This peptide is a potent competitor of the virus to gp120 binding, and inhibits viral infectivity and blocks the neurotoxic effect of gp120. In addition, peptide T is structurally similar to the neurotransmitter vasoactive intestinal peptide, and may be able to inhibit the production of tumor necrosis factor alpha.

Peptide T was evaluated in a phase I trial of 14 patients who were given intravenous drug for 12 weeks (Bridge et al., 1991). In addition, 6 of the initial 14 received 8 weeks more of intranasal peptide. Results were compared with untreated controls. Findings include increments in cognitive and neuromotor function as well as weight gain of about 2 kg, and improved sense of wellbeing. No significant toxicity was reported. This small study provided the rationale for phase II testing.

A double-blind, placebo-controlled, trial in patients with evidence of cognitive deficit was performed using intranasal peptide (Heseltine et al., 1998). The drug was administered three times a day for six months, and the primary outcome was changes in a score of 23 neuropsychological tests. At the end of the study, there was no significant difference between the treated and placebo groups, however there was some suggestion of cognitive improvement among those patients who had more severe cognitive impairment and those with relatively higher CD4 cell counts. There were significant differences in the development of mood disorders such as depression and irritability, and presence of severe rash in the peptide T group.

41.5.8. Selegiline

Cytokines, such as tumor necrosis alfa and oxygen radicals, may be produced by HIV-infected macrophages or microglia. These substances cause apoptosis in the cerebral cortex and basal ganglia. Selegiline, also called deprenyl, and thioctic acid are monoamine oxidase-B inhibitors that have antioxidative effects and have been evaluated in two clinical trials. Deprenyl has been previously studied in patients with Alzheimer's dementia and Parkinson's disease, showing improvement of memory in these conditions.

A study by the Dana Consortium used deprenyl and thioctic acid in 36 patients with HIV-associated cognitive impairment (The Dana Consortium, 1998). Both medications were well tolerated. The deprenyl group showed some improvement in memory function, with improvement seen on the Rey Auditory Verbal Learning Test. However, other tests of psychomotor speed did not improve significantly. The mechanism of action of deprenyl is not clear, but it may have a trophic effect on injured neurons and may also suppress the formation of free radicals.

A second study used a transdermal system of selegiline administration, which provides constant and higher plasma levels of the drug (Sacktor et al., 2000). Participants were either placed on selegiline or placebo. Selegiline was well tolerated, and the selegiline group did better than the placebo group on some components of the Rey Auditory Verbal Learning Test, however other tests of psychomotor speed, like Cal Cap mean reaction time, Digit Symbol, or Grooved Pegboard, did not improve. Also, there was no significant impact on the functional status of the patients. The study results prompted development of a larger, double-blind, placebo-controlled trial which failed to show evidence of cognitive or functional improvement (Schifito et al., 2007b).

41.6. Additional Management Considerations

41.6.1. Importance of Adherence to Antiretroviral Therapy

ART is the treatment of choice for HAD as this option improves both cognitive function, and overall survival. Adherence to therapy is therefore a crucial issue in this population. Surveys of adherence among HIV-infected patients have showed a percentage of non-adherence ranging from 22% to 59% (Gallant and Block, 1998; Rodriguez-Rosado et al., 1998). Factors that influence adherence to ART include: younger age, African American ethnicity, male sex, lower level of general education, and poorer literacy. In addition, patient beliefs and knowledge about the disease and its treatment may impact adherence. Finally, the physical and psychological condition of patients and the stage of HIV infection also determine non-adherence (Gordillo et al., 1999; Paterson et al., 2000; Castro, 2005). While no studies have specifically targeted adherence levels in patients with HAD, cognitive deficits have been shown to have a negative impact on adherence (Swindells, 2005).

Providers can help to improve treatment adherence by paying attention to issues such as patients' lifestyle/needs, and avoidance of polypharmacy and drugs that may have higher risk of adverse effects. Dietary constraints with certain drugs need to be taken seriously since some patients may be unable to comply with them. Patient education is an important strategy in improving adherence because it improves motivation and intention to adhere to the regimen as prescribed (Williams and Friedland, 1997). Simple reminder devices, such as a portable medication alarm or pill organizers, may be valuable but they may be too sophisticated in certain situations. Use of cues such TV programs or certain daily routines have proven useful (Chesney, 1997). Recently, a programmable prompting device improved adherence to ART in HIV-infected subjects with memory impairment (Andrade et al., 2005). A multidisciplinary team offering a trusting and respectful approach to the patient may be of significant value in improving compliance by implementing strategies for solving potential problems.

41.6.2. Supportive Care

The impact of short-term educational programs in patients and caregivers is usually modest, however, intensive long-term educational programs and support programs for caregivers may delay the time of admission to a nursing home by 12–24 months. Certain non-pharmacological interventions may improve functional performance of patients with dementia. Behavior modification, scheduled toileting, and prompted voiding can reduce urinary incontinence, whereas graded assistance, skills practice, and positive reinforcement can increase functional independence. Patients with HAD may benefit from art therapy, sensory stimulation and other

psychosocial interventions, but the impact of such activities is difficult to measure. In addition, education, support and respite care for caregivers improve their emotional well being and quality of life and helps in delaying nursing home placement for patients with dementia.

Summary

Although less common in recent years, HAD remains a challenging condition for patients, families and care providers. Specific diagnostic tests are still lacking. Despite many years of thoughtful investigation and effort, advances in our understanding of the neuropathogenesis of HAD have yet to translate into significant clinical utility. The most noteworthy improvements in treatment of cognitive impairment have come from widespread use of combination ART. Even though many of the most potent compounds have little to no penetration into CSF, control of virus replication in the periphery appears to be sufficient to arrest or reverse the course of HAD. For some patients with chronic neurological disease, changes may irreversible and improvement only modest. In addition, HAD may develop in treated patients, albeit at later stages of disease.

Review Questions/Problems

1. Which of the following drug classes are not currently licensed for the treatment of HIV disease?
 - a. Nucleoside reverse transcriptase inhibitors
 - b. Non-nucleoside reverse transcriptase inhibitors
 - c. Protease inhibitors
 - d. Entry inhibitors
 - e. Inhibitors of viral maturation
2. A patient with HIV-associated dementia was started on antiretroviral therapy two weeks ago. He complains of dizziness, insomnia, and vivid dreams. This reaction is most likely related to the use of:
 - a. Zidovudine
 - b. Tenofovir
 - c. Lamivudine
 - d. Efavirenz
 - e. Nevirapine
3. Which of the following class of drugs is not recommended for first line therapy in patients with HIV-associated dementia?
 - a. Nucleoside reverse transcriptase inhibitors
 - b. Non-nucleoside reverse transcriptase inhibitors
 - c. Protease inhibitors
 - d. Entry inhibitors
 - e. All can be used as first line agents in the treatment of HAD
4. Contemporary treatment of HIV infection requires the use of two nucleoside reverse transcriptase inhibitors (NRTI) combined with either a non-nucleoside reverse transcriptase inhibitors or a protease inhibitor. Which of the following NRTI backbones will you prefer to use in a patient recently diagnosed with HIV-associated dementia:
 - a. Zidovudine plus stavudine
 - b. Zidovudine plus lamivudine
 - c. Zalcitabine plus didanosine
 - d. Zalcitabine plus lamivudine
 - e. Didanosine plus tenofovir
5. Which of the following combinations will not be recommended for first line therapy in a patient with HIV associated dementia?
 - a. Zidovudine plus lamivudine plus efavirenz
 - b. Tenofovir plus emtricitabine plus lopinavir/ritonavir
 - c. Tenofovir plus emtricitabine plus atazanavir/ritonavir
 - d. Lamivudine plus abacavir plus fosamprenavir
 - e. Zidovudine plus lamivudine plus abacavir
6. Which of the following nucleoside reverse transcriptase inhibitors has the best penetration into CSF?
 - a. Zidovudine
 - b. Didanosine
 - c. Lamivudine
 - d. Stavudine
 - e. Abacavir
7. A patient with HIV-associated dementia receiving antiretroviral therapy presents with a burning sensation in feet and hands, numbness and tingling in the feet, cramps in the legs, and absent ankle reflexes. What drug will you be the LEAST likely to blame on his/her new symptoms?
 - a. Zidovudine
 - b. Stavudine
 - c. Didanosine
 - d. Zalcitabine
 - e. All of the above can cause the patient's symptoms
8. Which of the following protease inhibitors is the most powerful inhibitor of the P450 enzyme?
 - a. Atazanavir
 - b. Fosamprenavir
 - c. Indinavir
 - d. Nelfinavir
 - e. Ritonavir
9. Which of the following drugs has been proven to be effective as adjuvant therapy for HIV associated dementia?
 - a. Lexipafant
 - b. Memantine

- c. Minocycline
 - d. Nimodipine
 - e. None of the above
 - f. All of the above
- 10. In a busy clinical practice setting, the simplest neuropsychological test to diagnose HIV dementia is?**
- a. Standard Mini-Mental Status test
 - b. HIV-dementia scale
 - c. Memorial Sloan Kettering Scale
 - d. Halstead-Reitan Neuropsychological Battery
 - e. San Diego HIV Neurobehavioral Research Center
- 11. HIV-associated dementia is also referred to as:**
- a. HIV dementia
 - b. AIDS Dementia Complex
 - c. Subacute encephalopathy
 - d. HIV-1-associated cognitive-motor complex
 - e. All of the above
- 12. What is correct about the “Trojan Horse” model of HIV invasion into the CNS?**
- a. Proposes that monocyte-macrophage carry progeny virions from blood to the brain inside cytoplasmic vacuoles and across the blood–brain barrier
 - b. Requires an inflammatory response in the brain, which elicits a chemokine gradient
 - c. After infiltrating the brain parenchyma, blood borne monocyte-macrophages also release additional chemokines and further attract additional inflammatory cells
 - d. Does not require productive viral replication in brain microvascular endothelial cells
 - e. All of the above
- 13. The clinical and laboratory features of HIV-associated dementia include all “except” which of the following?**
- a. Psychomotor slowing
 - b. History of HIV related disease
 - c. Extrapyramidal symptoms
 - d. Depression
 - e. Reduced viral loads and serum beta 2 microglobulin
- 14. What is not correct in regards to a diagnosis of HIV-associated dementia?**
- a. HAD is a diagnosis of exclusion
 - b. HIV does elicit an inflammatory response. This can be detected by mild lymphocytic pleocytosis, elevation of total protein, increase of total IgG, and/or the presence of oligoclonal bands
 - c. HAD is always associated with a concurrent diagnosis of progressive multifocal leukoencephalopathy
 - d. HAD almost always is associated with CD4⁺ T cell counts of less than 600
 - e. The clinical manifestations of HAD include behavioral, cognitive, and/or motor abnormalities
- 15. What aspects of clinical care have impacted the natural history of cognitive impairments in HIV infected individuals?**
- a. The introduction of potent, combination anti-retroviral therapy
 - b. The use of prophylactic medications against opportunistic infections
 - c. Improved biomarkers for disease diagnosis
 - d. One and two
 - e. None of the above
- 16. Antiretroviral agents currently in use include inhibitors of reverse transcriptase, HIV protease, and fusion inhibitors.**
- True/False
- 17. Currently there are six classes of antiretroviral agents available in the United States for clinical use:**
- Nucleoside analogue reverse transcriptase inhibitors
 - Nonnucleoside analogue reverse transcriptase inhibitors
 - Protease inhibitors
 - Entry inhibitors
 - Tat inhibitors
 - Nef inhibitors
- True/False
- 18. Nucleoside analogue reverse transcriptase inhibitors are drugs of diverse chemical structure that act by non-competitive inhibition of HIV-1 reverse transcriptase.**
- True/False
- 19. Recent guidelines for starting anti-retroviral therapy recommend that patients with advanced disease, as manifested by the development of an AIDS-defining illness including HAD, or presence of severe symptoms such as unexplained fever, persistent diarrhea, or unexplained weight loss, should be started on ART if their CD4⁺ T cell count is <100.**
- True/False
- 20. Abacavir plus lamivudine plus zidovudine, which is commercially available as a fixed combination in a single tablet, has inferior rates of viral suppression and should only be used when an NNRTI or a PI-based regimen cannot or should not be used as first line of therapy.**
- True/False

42.1. Introduction

The central nervous system (CNS) has been referred as an immune privilege, in which local immune responses are restricted (Hailer et al., 1998; Cohen and Schwartz, 1999; Neumann, 2000; Pachter et al., 2003; Villoslada and Genain, 2004; Hatterer et al., 2005). Unlike most peripheral tissues, the CNS functions through a network of post mitotic cells (neurons) that are incapable of regeneration and hence any immune activity might interfere with cell function. CNS is vulnerable to damage that might be caused by the very means that the immune system uses to defend peripheral tissues from pathogens. Consequently, immune privilege in the CNS has been viewed as an evolutionary adaptation developed to protect the intricate neuronal networks of the CNS from incursion by the immune system (Lotan and Schwartz, 1994; Lotan et al., 1994).

An early definition of CNS immune privilege was based on the assumption that the access of immune system is restricted to the CNS. This assumption was supported by the observed tendency of a very slow rejection of allografts in the CNS (Fuchs and Bullard, 1988; Rao et al., 1989; Broadwell et al., 1990, 1994). Any leukocyte entry into CNS was viewed as evidence of pathology. Several observations have challenged this definition. Firstly, CNS antigens are drained to peripheral (cervical) lymph nodes and induce immune responses in the host (Cserr et al., 1992a, b; Cserr and Knopf, 1992). Second, activated T cells have been found to enter the CNS in the absence of discernible neuropathology (Hickey, 1999; Flugel et al., 2001). Third, leukocyte recruitment into the CNS appears to successfully resolve some CNS viral infections, such as Sindbis virus encephalitis, without the development of any apparent long-term bystander effects (Griffin et al., 1997; Griffin and Hardwick, 1997). Fourth, based on

the relatively prolonged survival of xenografts (tissue grafts from different species) in immunosuppressed individuals, it was suggested that the immune system participates in CNS xenograft rejection (Czech et al., 1997). Taken together, these findings indicate that the CNS is accessible to immune cells, and that local immune responses within the CNS are regulated by a number of mechanisms. It seems likely that some of these mechanisms help to limit immune responses, with vital consequences for the functioning of the healthy CNS, however these mechanisms are altered following injury or under other devastating neurodegenerative disorders, thus making injured CNS friendlier and more assessable to immune cells. This includes up-regulation of major histocompatibility complex (MHC) class I and II molecule expression, down-regulation of Fas expression and increased permeability of blood–brain barrier (BBB) (Moalem et al., 1999a).

42.2. Immune Modulation in Neurodegenerative Disorders and Neural Injuries

Acute mechanical or biochemical injury to the mammalian CNS often results in an irreversible functional deficit (Schwab and Bartholdi, 1996; Cottrell et al., 1999; Schwab et al., 2000; Vinters et al., 2000; Gaviria et al., 2002) for several reasons, including the poor ability of injured axons to regrow, and a destructive series of injury-induced events that result in the spread of damage to neurons that escaped the direct injury (Faden, 1993; Faden et al., 1993; Povlishock and Christman, 1995; Povlishock and Jenkins, 1995; Yoles and Schwartz, 1998a; Hauben et al., 2000). This spread of damage is known as secondary degeneration. Attempts to promote CNS recovery have focused on two goals: (1) stimulation of regrowth (Caroni et al., 1988; Caroni and Schwab, 1988; Reier et al., 1992; Cheng et al., 1996; Rapalino et al., 1998; Chong et al., 1999; Neumann and Woolf, 1999), and (2) neuroprotection, or the arrest of self-perpetuating degeneration (Hall et al., 1992; Stolc et al., 1997; Lipton et al., 1998;

Yoles and Schwartz, 1998b; Robertson et al., 2000; Roof and Hall, 2000; Schwartz, 2000; Schwartz and Yoles, 2000; Legos et al., 2001; Schwartz, 2001; Schwartz and Kipnis, 2001, 2002; Vajda, 2002; Bialek et al., 2004; Murray et al., 2004; Wu, 2005). The extent of recovery, in the absence of intervention, is a function of the amount of tissue that escaped the initial injury minus the loss associated with a neurodegenerative process of secondary degeneration. Thus the outcome is significantly worse than could have been predicted by the severity of an initial injury, however, could be reduced if initially undamaged or only marginally damaged neurons are rescued from secondary degeneration. Recognition of this fact and comparative ease of achievement as opposed to regeneration, has led to the emphasis on neuroprotection in the approach to CNS therapy. The spread of damage is mediated by numerous factors, among which are glutamate, nitric oxide, deprivation of growth factors, impaired blood supply and thus general metabolic deficit and others. Similar factors operate in different insults and across species, suggesting that the progression of damage might reflect a loss of control over mechanisms that regulate self-components, which, though normally essential, contribute to the damage spread under pathological conditions or at concentrations that exceed physiological. The increased presence of infiltrating or activated immune cells that accompanies degeneration often led scientists and clinicians to conclude that these cells contribute to the pathology and thus immune-suppressive therapies have emerged, without in-depth understanding of the mechanisms underlying their neuroprotective effects. Corticosteroids are the most widely used immune suppressive drugs for neurodegenerative disorders (Faden and Salzman, 1992; Hirschberg et al., 1994; Faden, 1996; Fung and Berger, 2000).

42.2.1. Corticosteroids for Glaucoma and Spinal Cord Injury

In physiology, corticosteroids are a class of steroid hormones that are produced in the adrenal cortex (De Nicola et al., 1998). Corticosteroids are involved in a wide range of physiologic systems such as stress response, immune response and regulation of inflammation, carbohydrate metabolism, protein catabolism, blood electrolyte levels, and behavior (Carlsen, 2005; Chamberlain et al., 2005; Currie et al., 2005; Schumacher and Chen, 2005; Williams, 2005). Corticosteroids have immune-suppressive properties and thus are used to suppress inflammation in the tissues and to suppress immune responses. Corticosteroids are also used to treat various neurodegenerative conditions assuming that suppression of post-injury inflammatory response at the site of injury will benefit tissue survival. Glucocorticoids are used frequently to suppress immunological responses and thus reports of the National Acute Spinal Cord Injury Studies (NASCIS) indicate that the standard method of treatment for patients with SCI currently includes the administra-

tion of high intravenous doses of methylprednisolone (MP) (Bracken et al., 1997). Recent reports question the benefit of corticosteroid treatment after CNS trauma; they also point out that the recommended MP dosage is the highest dose of steroids ever used during a 2-day period for any clinical condition, and therefore carries a risk (Hurlbert, 2000; Qian et al., 2000; Short, 2001). Other groups have shown that MP exacerbates axonal loss after optic nerve crush injury in Sprague-Dawley rats (Steinsapir et al., 2000). Corticosteroids are also used in ocular disorders and administered topically for diseases of the outer eye and anterior segment. Topical glucocorticoid therapy frequently increases intraocular pressure in normal eyes and exacerbates intraocular hypertension in patients with glaucoma. The glaucoma is not always reversible on cessation of glucocorticoid therapy (Kanagavalli et al., 2004; Kersey and Broadway, 2005; Kuchtey et al., 2005).

42.2.2. Cyclosporine A and Neurodegenerative Disorders

Cyclosporine A is another immunosuppressant drug. It is used post-allogeneic organ transplant to reduce the activity of the patient's immune system and so the risk of organ rejection. It has been studied in transplants of skin, heart, kidney, lung, pancreas, bone marrow and small intestine. Cyclosporine A (CsA) was also used to treat various neurodegenerative disorders, among which are Amyotrophic Lateral Sclerosis, Alzheimer's and Parkinson's diseases and acute CNS injuries. The micro and macro mechanisms underlying neuroprotection mediated by CsA are not fully understood. CsA has been shown to promote neurite outgrowth in cultured PC12 cells and sensory ganglia. Moreover, application of CsA following spinal cord injury increased GAP-43 expression, a sprouting marker, which was associated with improved functional recovery. CNS injury leads to mitochondrial dysfunction and thus mitochondria isolated from injured CNS show an increased production of reactive oxygen species. Treatment with CsA significantly attenuated mitochondrial dysfunction. In addition, CsA blocks a calcium-induced axonal damage, thus the effect of CsA could be mediated directly via restoration and maintenance of ionic and mitochondrial homeostasis, and not necessarily via suppression of immune response, as was originally thought.

While preclinical data from CsA in neurodegenerative disorders was promising, larger studies in Parkinson's disease did not show any benefit along with side complications. Major neurological complications secondary to cyclosporine are well documented and are known to include confusion, cortical blindness, seizure, spasticity, paresis, ataxia and coma. Most previous reports attribute these to white matter CNS lesions or white/grey matter border lesions. Moreover, several publications appeared recently refuted neuroprotective properties of CsA and similar compounds (immunophilin ligands).

So far, none of the immune suppressive drugs showed a significant and stable neuroprotective effects in any of the neurodegenerative conditions. Moreover, under those conditions when steroids were protective they were suggested to mediate the effect directly rather than via suppressing the immune system.

42.3. Immunomodulatory Therapeutics

42.3.1. T Cell Vaccination

Being not fully satisfied by the immune suppressive therapies and having side complication as a result of these compounds, the idea of modulating rather than suppressing an immune response has been evolved. Very first modulation of immune response was undertaken to treat autoimmune conditions such as multiple sclerosis in animal models of Experimental Autoimmune Encephalitis (EAE). The rationale and practice of T cell vaccination (TCV) against devastating processes underlying pathological autoimmune inflammation was analogous to classical vaccination against infectious disease. However, TCV differs from classical vaccination, as the “pathogen” is the identification marker of patient’s own T cell receptor. The vaccine is devised using a component of the immune system itself – creating an autoimmune response against autoimmune T cells. For example, a single inoculation of myelin basic protein (MBP) reactive T cells, previously irradiated, into animals, abrogated an ability to induce autoimmune disease in these recipients. T cells vaccination has been extended to other experimental conditions, like adjuvant arthritis, experimental autoimmune thyroiditis, collagen-induced arthritis, autoimmune uveitis, lupus and diabetes. Therefore, activation of autoimmune T cells against autoimmune T cells causing the disease. It is, however, still a matter of debate whether suppression of autoaggressive T cells, their modulation or the activation of autoimmune T cells due to TCV are the reason for the obtained amelioration of autoimmune destructive symptoms.

42.3.2. Naturally Occurring CD4+ CD25+ Regulatory T Cells

Suppressor T cells are the hot topic of immunology for over last 20 years. Many types of regulatory T cells exist, however, all could be divided into two major populations: naturally occurring regulatory T cells and induced regulatory T cells. While many pathways have been recently elucidated to induce regulatory T cells to treat various autoimmune and neurodegenerative disorders, it is still a matter of debate whether regulatory or suppressor T cells are induced naturally in humans. The sub-population of T cells, termed naturally occurring regulatory T cells (Treg) and bearing a marker of CD25 in their naïve state, exists in both rodents and humans and account for 10% of total CD4+ T cell population. Tregs are also exclusively express Foxp3, transcription factor (Schramm et al., 2004; Viguier et al., 2004; Gavin et al., 2007). Treg cells are antigen specific anergic cells and the

mechanism of inhibition requires both soluble factors and cell-to-cell contact. While the biology and the suppressive mechanism of these regulatory T cells are highly complicated and not fully understood, their practical application has been shown in several animal models of autoimmune and neurodegenerative disorders. Injection of Treg cells improved the outcome of EAE in mice. Treg cells accumulated in the site of autoimmune lesion and suppressed autoaggressive T cells. Application of Treg was shown to benefit colitis, autoimmune diabetes and other autoimmune disease. The role of these cells under neurodegenerative conditions is dual – while Treg cells protect neurons directly under certain circumstances, they suppress beneficial inflammatory response under other circumstances and thus exacerbate neuronal survival. Interestingly, injection of these cells into injured mice prone to develop autoimmune disease EAE, increased neuronal survival, whereas in strains that are resistant to EAE, an opposite effect has been obtained. Thus immune modulation using suppressor T cells will most probably benefit patients with autoimmune-mediated neurodegenerative disorders, however, will not be applicable for general population.

Treg cells bear markers of activated cells (e.g. CD25) in their naïve form, therefore, while these cells can be isolated from naïve mice, their isolation from patients with any inflammatory disease is technically impossible, due to the fact that activated effector (non-regulatory) T cells will bear markers identical to those expressed by Treg cells. Therefore, Treg mediated immune modulation does not seem feasible, at least now, until better markers are developed for Treg isolation from a pool of activated CD4+ T cell lymphocytes.

42.3.3. Induction of Regulatory T Cells by Mucosal Immunization

To overcome the need for isolation, activation and re-injection of Treg cells, alternative ways have been developed aimed to induce regulatory T cells or T cells with regulatory phenotype from normal CD4+ effector T cells. The most established approach is induction of mucosal tolerance that gives rise to T cells with anti-inflammatory phenotype, expressing mainly IL-10 and TGF- β cytokines. Evolutionary, mucosal tolerance allows prevention of the immune response toward orally (and nasally) consumed proteins, or in other words, to avoid immune allergy for consumed food. Taking advantage of this natural way to induce anti-inflammatory T cells, self-antigens were given orally in animals suffering from experimental autoimmune diseases. Such for example, mice fed orally with MBP were protective from induction of EAE using conventional vaccination techniques, otherwise inducing autoimmune syndromes. Later, this approach of modulation of immune response by induction of mucosal tolerance was examined on animal models for neurodegenerative disorders. Modulation of autoimmune inflammation, frequently associated with neurodegenerative disorders, was obtained by mucosal (oral or nasal) immunization with proteins abundantly expressed at the site of neurodegeneration, for example, myelin antigen for white matter injuries, retinal proteins for ocular

neurodegenerative diseases, etc. Such mucosal vaccination was shown to benefit neuronal survival following acute injuries and chronic neurodegenerative conditions. One concern regarding mucosal vaccination, similar to previously raised concern with regulatory T cell therapy, is that immune response to injury is dependent on many factors and varies among individuals, therefore, mucosal tolerance might not be applicable clinically for use in general population.

42.3.4. Copaxone

Another approach to modulate immune response was initiated in early 70's when artificial compounds (polymers) were synthesized to mimic antigens and thus to induce immune response with partial cross reactivity to self-antigens. Partial recognition of antigen induces either an anti-inflammatory response or leads to anergy. Based on this understanding a synthetic co-polymer (Cop-1) has been synthesized (4.7–11 kDa) from four amino acids: L-alanine, L-lysine, L-glutamic acid and L-tyrosine, in a molar ratio of 4.2:3.4:1.4:1.0, aimed to mimic a dominant epitope of MBP—the most abundant myelin protein. Immunization with Cop-1 induced a T cells response partially cross-reactive with myelin basic protein, however did not induce an autoimmune disease. Moreover, immunization with MBP did not induce EAE if Cop-1 was mixed into the emulsion. Thus, Cop-1 was developed as a drug for multiple sclerosis and was later approved by Food and Drug Administration (FDA). Cop-1 is given daily to MS patients by sub cutaneous injection and has very limited side effects. The mechanism underlying Cop-1 mediated anti-inflammatory effect is based on clonal expansion of T cells with partial cross-reactive with MBP and a strong Th2 phenotype. Thus, Cop-1 reactive T cells were proposed to affect the ongoing inflammation by secretion of anti-inflammatory cytokines, phenomenon named “bystander suppression”. Another possible explanation is the ability of Cop-1 to bind to MHC molecules from outside, without being processed, thus displacing dominant myelin proteins and being presented to MBP reactive T cells. Due to non-complete matching between the T cell receptor and the antigen (Cop-1 rather than MBP) the activation of T cells is not complete and such activation induced cellular anergy (no ability to respond or proliferate) or a very strong anti-inflammatory phenotype.

Recently Cop-1 was assessed for its neuroprotective properties, due to its partial cross-recognition with myelin basic protein. Immunization with Cop-1 significantly improved neuronal survival following acute injury of myelinated central and peripheral neurons. Recently Cop-1 was found to be neuroprotective also under various chronic conditions and under severe mental dysfunctions. While the mechanism for its neuroprotective properties is not well understood, it was shown that immunization with Cop-1 induces T cells that can pass through the Blood-Brain Barrier and to accumulate in the injured site. Upon migration to the brain, these cells induce production of growth factors by glial cells as well as

produce these factors by themselves. The major growth factor produced and induced by Cop-1 reactive T cells in the brain in the Brain Derived Neurotrophic Factor (BDNF).

42.4. Vaccination for Neurodegenerative Disorders

42.4.1. Harnessing Humoral Immune Responses for Treatments of Spinal Cord Injuries and Alzheimer's Disease

Research over the last few years has demonstrated that myelin-associated inhibitor proteins inhibit sprouting and regeneration in the injured CNS. Antibodies neutralizing myelin inhibitors have been shown to improve spontaneous sprouting and regrowth (Schnell and Schwab, 1990) of injured CNS fibers. Among the factors found to be hostile to regrowth in adult CNS nerves are myelin-associated proteins (Schnell et al., 1999; Schwab et al., 2002; Schwab, 2002; He and Koprivica, 2004; Schwab et al., 2004; Buss et al., 2005) and extracellular matrix proteins such as chondroitin sulfate proteoglycans (CSPG) (Snow et al., 1990; Zuo et al., 1998). Accordingly, for regeneration to occur, these inhibitors must be masked, neutralized, or eliminated. Monoclonal antibodies directed specifically against the myelin-associated inhibitor IN-1 were introduced into partially transected rat spinal cords, with consequent promotion of regeneration (Schnell and Schwab, 1990). More recently it was demonstrated that immunization with myelin-associated proteins, such as NoGo, results in regeneration mediated by antibodies (Ellezam et al., 2003; Skaper, 2005). Interestingly, antibodies to myelin basic protein also were shown to lead to efficient myelin clearance and thus to facilitate recovery by preventive immunization or by passive transfer of specific antibodies (Huang et al., 1999; Ousman and David, 2001; Wong et al., 2003).

Use of antibodies to treat neurological disorders is not restricted to spinal cord injuries and was pioneered in Alzheimer's Disease (AD) research (Imahori and Uchida, 1997; Duyckaerts et al., 1998; Solomon, 2002; Heppner et al., 2004). In AD patients, or in animal models for AD, among various factors causing neurodegeneration, Amyloid- β aggregates are considered to be the major factor (Blass and Gibson, 1991; Richards et al., 1991; Bard et al., 2000). It is agreed that boosting of resident macrophages (microglia) to clear the plaques would benefit disease outcome. The performance of anti-A β -antibodies in transgenic mice models of AD prevented formation of new and induced dissolving of existing A β plaques (Lambert et al., 2001; Kotilinek et al., 2002; Mohajeri et al., 2002b; Mohajeri et al., 2002a; Nicolau et al., 2002; Rockenstein et al., 2002; Sigurdsson et al., 2002). Moreover, these antibodies protected the mice from learning and age-related memory deficits. Naturally occurring anti-A β antibodies have been found in human CSF and in the plasma of healthy individuals, but were significantly lower in AD patients, suggesting that AD patients cannot

induce a desired immune reactivity to A β plaques and therefore develop a disorder (Monson et al., 2003). Active and/or passive immunization against A β peptide has been proposed as a method for preventing and/or treating Alzheimer's disease (Das et al., 2003; Frenkel et al., 2003; Furlan et al., 2003; Ghochikyan et al., 2003; Gong et al., 2003; Liu et al., 2004; Manea et al., 2004; Butovsky et al., 2005; Chauhan and Siegel, 2005; Faden et al., 2005). Experimental active immunization with A β 1–42 in humans was stopped in phase II clinical trials due to unexpected neuroinflammatory manifestations and death associated with the treatment (Koistinaho et al., 2001; Tariot and Federoff, 2003). Although the trials have been stopped, post-mortem observation of the tissue showed a significant drop in the number of plaques in treated patients. Therefore, there is a hope of developing better antibodies with similar therapeutic potential without such devastating side effects.

Although immune cells are known to play a key role in tissue repair, their activity in the CNS, as outlined above, has mostly been viewed as detrimental. A comparative study of the local inflammatory response in injured peripheral nervous system and CNS axons revealed that in the injured peripheral nervous system (PNS), where regeneration takes place spontaneously, both degeneration and regeneration appear to be brought about and controlled with the prominent participation of macrophages. Macrophages are also a source of cytokines and growth factors that actively participate, both directly and indirectly, in regrowth. As an example, the regeneration of optic nerves in lower vertebrates, as well as of peripheral nerves in mammals, was found to correlate with upregulation of macrophage-derived apolipoproteins, which participate in the recycling of lipids needed for membrane rebuilding (Ignatius et al., 1987; Harel et al., 1989). Similarly, the synthesis of nerve growth factor seems to be regulated by stimulated macrophages. IL-1 and tumor necrosis factor (TNF)- α , both secreted by macrophages, probably induce nerve growth factor transcription in Schwann cells (Lindholm et al., 1987).

In early experiments aimed at boosting of the innate response in the injured CNS to facilitate better phagocytosis of myelin debris, it was found that implantation of homologous macrophages in the completely transected spinal cords of adult rats, it was demonstrated partial recovery of motor function (manifested by locomotor activity scored in an open field) and electrophysiological activity (assessed by motor-evoked potential responses) (Rapalino et al., 1998). These behavioral manifestations were also reflected in the electrophysiological recovery of motor-evoked potential responses in the implanted rats.

42.4.2. Innate and Adaptive Immunity

The first line of defense in any injured tissue is the innate immune response, characterized by activity of the phagocytic immune cells (Paape et al., 2000), however, this response is tightly controlled by adaptive immunity, namely T cells. There are different subpopulations of CD4+ T cells, each responsible for a certain type of immune response. Th1 cells, for example,

reinforce cellular immunity, whereas Th2 cells induce humoral (antibody-mediated) immunity. Studies have shown that the autoimmune CD4+ T cells locally boost and control resident microglia and infiltrating blood-borne monocytes, helping them to acquire an activity that allows them to fight off degenerative conditions. It also allows them to buffer toxic compounds without producing excessive amounts of inflammation-associated cytotoxic compounds such as TNF- α , nitric oxide (NO), or cyclooxygenase (COX)-2 (Levi et al., 1998; Basu et al., 2002; Janabi, 2002; Schwartz, 2003), and to produce growth factors such as insulin-like growth factor-1 that are critical for neuronal survival and renewal. Thus, the role of CD4+ T cells directed against self-antigens is to activate the innate response in a well-controlled way, enabling it to recognize the threat to the tissue not as a harmful organism that it must kill, but as a toxic substance that it must neutralize or eliminate. In addition, the T cells themselves, if locally activated, can produce protective compounds such as growth factors and neurotrophins (Hammarberg et al., 2000; Moalem et al., 2000; Gielen et al., 2003). All of these tasks can be accomplished by a well-controlled response by Th cells. These cells, in order to do their job, must first home to sites of stress and be locally activated by their specific antigens that reside there. Thus, the homing of T cells to the site at which their local activation can occur is apparently dictated by antigenic specificity. In line with this notion are the findings that T cells having the same antigenic specificity are protective against different types of threatening stimuli occurring at the same site, or against different threatening stimuli at different sites sharing the same immunodominant, constitutively expressed self-proteins (Mizrahi et al., 2002). As a corollary, the same threatening stimulus, if manifested at different sites that do not share common dominant self-antigens, does not benefit from T cells directed against the same antigen (Schori et al., 2001; Mizrahi et al., 2002).

Studies from several laboratories have shown that T cells patrol the healthy CNS but do not accumulate there (Hickey, 1999; Flugel et al., 2001). In the event of an acute injury or chronic neurodegenerative conditions, T cells are recruited by and accumulate in the CNS (Hirschberg et al., 1998; Moalem et al., 1999a), where they might rescue neurons from degeneration if the damage caused by the toxic biochemical environment is not yet irreversible; moreover, the recruited T cells will prevent further deterioration. It is possible that this autoimmune protective mechanism also operates when the threat to the tissue comes from microbial infiltration. In such a case the anti-self response is additional to the anti-microbial response, and might occur without the individual even being aware of it, unless the harnessed autoimmunity gets out of control, in which case its effect is no longer beneficial but destructive, and might result in an autoimmune disease (Schwartz, 2002). This might be the situation in individuals who are predisposed to autoimmune disease development (Kipnis et al., 2001). According to this view, the pathogenic self-proteins that have been implicated in autoimmune diseases are the same proteins against which a well-controlled T-cell response is protective (Moalem et al., 1999b; Kipnis et al., 2002b). It might explain

the generally low clinical prevalence of autoimmune diseases and their occurrence mainly in young adults rather than in the elderly population, whereas neurodegenerative diseases and cancer are common and significantly more prevalent in the elderly, in whom the immune system is deteriorating (Linton and Dorshkind, 2004). Boost of autoimmune activity following injury increases the number of surviving neurons, however, it has a risk of development of autoimmune disease. Alternative approach is to boost an immune response with cross-reactivity with self antigens, such as with Cop-1. Immunization with Cop-1 is neuroprotective in various acute and chronic neurodegenerative conditions (Kipnis et al., 2000; Schori et al., 2001; Angelov et al., 2003; Benner et al., 2004; Frenkel et al., 2005). Therefore various ways are searched now to find the best approach under which the boost of autoimmune T cells or of T cells with partial recognition to self-antigens would lead to maximum benefit with minimal destructive consequences of autoimmune disease. These possible therapeutic approaches are discussed in details in the following chapter (Kipnis et al., 2002a).

Summary

From the “immune privilege” status and immunosuppressive treatments considered for almost any neurodegenerative conditions, our understanding of the neuro-immune interactions underwent a significant evolution and current therapies are aimed to modulate and boost rather than suppress and eliminate immune assistance in the brain.

Review Questions/Problems

1. Myelin can cause neuronal growth inhibition.

True/False

2. Injured CNS fibers have the potential for regrowth.

True/False

3. T cells required for neuroprotection are antigen specific.

True/False

4. Naturally occurring regulatory CD4⁺ CD25⁺ T cells are derived from the thymus.

True/False

5. Glutamate is a part of both killing machinery and neuronal communication

True/False

6. Immune synapses in the CNS are MHC-II-expressing microglia interacting with T-helper lymphocytes.

True/False

7. Macrophages that can promote regeneration after a spinal cord injury should primarily be

- a. cytotoxic
- b. antigen presenting
- c. phagocytic
- d. naïve
- e. all of the above

8. Autoimmune T cells required for protection of the injured spinal cord are reactive toward

- a. skin proteins
- b. heat-shock proteins
- c. myelin proteins
- d. their antigenic specificity is irrelevant to the type of injury

9. Mucosal tolerance can be viewed as

- a. modulation of immune response
- b. suppression of immune response
- c. boost of the immune response
- d. all of the above
- e. none of the above

10. Immunization with Copaxone can be viewed as

- a. modulation of immune response
- b. suppression of immune response
- c. boost of the immune response
- d. all of the above
- e. none of the above

11. Spinal cord injury is associated with

- a. axonal regrowth
- b. inhibition of axonal regrowth
- c. axonal sprouting
- d. none of the above

12. Neuroprotection induced by CsA under certain neurodegenerative conditions can be attributed solely to

- a. suppression of the immune response
- b. activation of the immune response
- c. induction of growth factors
- d. direct effect on glial cells
- e. none of the above

13. The role of immune cells in the CNS – is it destructive or protective? What are benefits of immune boost following injury and what are the possible devastating side effects of such therapy?

14. What is immune modulation and how it could be achieved?

15. Immune suppression is neuroprotective under certain circumstances whereas neurodestructive under others. How this apparent dichotomy could be resolved?

16. What is the evolutionary benefit from having a complex network of autoimmune and regulatory T cells?

17. Does the presence of BBB favors in favor or not of the role of immune system in post-injury recovery?

Alzheimer's Disease

Dave Morgan and Marcia N. Gordon

Keywords Active vaccination; Alzheimer's disease; Amyloid; Amyloid precursor protein; Antibody titer; Beta-pleated sheet; Cerebral amyloid angiopathy; Dementia; Immunotherapy; Monoclonal antibody; Passive vaccination; Senility

43.1. Introduction

Historically, the condition of dementia first described by Alois Alzheimer in 1907 was called generically "presenile dementia." This nomenclature distinguished Alzheimer's as a disease, and not the dementia that occurred typically as humans reached advanced years, known commonly as "senility." It was believed that all of us would develop senility after living long enough, and that this was a normal part of the aging process.

One of the defining characteristics of Alzheimer's was its pathology, consisting of senile or neuritic plaques and intracellular inclusions termed neurofibrillary tangles (see below). In the last quarter of the last century it became increasingly clear that many cases of "senile dementia" also had these same plaques and tangles common to the presenile form described by Alzheimer. This led to terminology referring to "senile dementia of the Alzheimer-type" to describe these late-onset cases. Ultimately, it became recognized that the pathologies Alzheimer reported were associated with dementias at any age, and the term "Alzheimer's disease" was used to describe any severe cognitive deterioration that was associated with plaque and tangle pathology. This nomenclature has held for roughly the last 2 decades.

Over this same period, the numbers of individuals diagnosed with Alzheimer's disease increased dramatically. In part, this was due to increased public awareness that severe cognitive deterioration was not normal human aging (senility) but a disease with specific pathological determinants. A second reason was the increasing number of humans living to the age of risk for developing Alzheimer's disease. Although his original patient was quite young (50s), the vast majority of Alzheimer victims are in their 70s and 80s when they begin to show symptoms. The average age of death of an Alzheimer patient is greater

than the age of death in the general population. In the past, these were survivors whose physiology protected them from cardiovascular disease and cancers (the leading causes of death for the last 50 years). Today, the remarkable medical success in retarding the age-adjusted incidence of cardiovascular disease has expanded the population reaching these later years, leading to increased numbers of demented patients (currently reaching 4 million in the US, or slightly more than 1 out of every 100 Americans). Medical care costs for Alzheimer patients, who average 10 years survival with the disease, total \$100 billion, or 7% of all medical costs in the US. The major reason this disease is so costly is that most are institutionalized for some period preceding their demise. It is estimated that if the onset of dementia could be delayed by as little as 5 years, this would save \$50 billion in medical costs (essentially the same as the new Medicare drug benefit). Clearly, effective therapeutic or preventative approaches to this disorder would provide clear benefits not only to the patients and their families, but the nation as a whole.

The pathology of Alzheimer's disease was initially described using silver stains of histological sections. This resulted from the success of the emerging photographic industry in the early part of the last century, where silver chemistry was worked out with great precision. The plaques and tangles described by Alzheimer were by definition, "argyrophilic," meaning they bound silver molecules, which could then be reduced chemically to reveal stained regions.

The neuritic or senile plaques, also now called compact plaques, are comprised of fibrils of a short peptide called the A β peptide. This 40–42 amino acid peptide aggregates in a beta-pleated sheet structure to form fibrils, which are themselves aggregated into these dense plaques. These fibrils are referred to as "amyloid" because they stain with a dye called Congo red. There are many types of amyloids in the body, all of which share the properties of beta-pleated sheet structures, fibril formation and binding of Congo red dye. One feature of the Congo red dye is that it will shift the plane of polarized light when bound to beta sheet structures, leading to a characteristic red-green birefringence when viewed through

FIGURE 43.1. Compacted parenchymal amyloid plaque in APP transgenic mouse hippocampus. Section was stained with Congo red and viewed with cross-polarized light. Total magnification $\times 400$.

crossed polarizing filters (Figure 43.1). Surrounding these amyloid plaques is a zone of degenerating neuronal processes called neurites. These neurites are swollen, apparently drawn towards the amyloid plaques, and contain proteins or modifications of proteins (such as phosphorylation) not normally found in the larger processes of neurons. In addition to the compacted amyloid plaques, this amyloid material could often be found in association with blood vessels, where it was called cerebral amyloid angiopathy.

In the mid 1980s, George Glenner and his team (Glenner and Wong, 1984) tried to determine the amino acid sequence of the amyloid deposits in Alzheimer's disease. He had already found that other forms of amyloid in the body consisted of small fragments of much larger proteins that aggregated in this beta-pleated sheet secondary structure. When he tried to sequence the amyloid from the compacted plaques, he found variable results because much of the material had been truncated at the N terminal used to initiate the sequencing. However, the vascular deposits were more uniform, and he sequenced a 40 amino acid peptide called A β . This led within a year to the identification of a previously uncharacterized parent molecule containing the A β peptide sequence called the amyloid precursor protein (APP). This molecule has a single transmembrane spanning domain and the bulk of the 700 amino acid protein is oriented towards the outside of the cell.

Neurofibrillary tangles proved more difficult to identify at the molecular level. They also were fibrillar aggregates of a protein, and they also had a great deal of beta-pleated sheet structure, including staining by Congo red. However, their location within cells precluded them from being referred to as an amyloid. It is now widely accepted that these neurofibrillary tangles are comprised of abnormally and excessively phosphorylated forms of the microtubule associated protein tau. These tau filaments are

TABLE 43.1. The genetics of Alzheimer's disease.

Type of Alzheimer's	Age of onset	Inheritance	Comments
Familial (<2%)	40s–50s	Autosomal dominant	Mutations in amyloid precursor protein, presenilin-1 or presenilin-2 account for most cases
Inherited risk (30–50%)	60s–70s	Not dominant	Apolipoprotein E4 allele increases risk (Earlier age of onset). Pathology more severe.
Sporadic (50–70%)	70s–80s	None identified	Increased risk, Head trauma; decreased risk, Education

largely insoluble by most known solvents, which slowed the identification of their major components.

A detailed account of the genetics of Alzheimer's disease is beyond the scope of this chapter. Others have detailed this quite thoroughly (Hardy, 1997). However, there are at least three genetically identifiable categories of Alzheimer's disease. The first are those rare cases in which Alzheimer's is caused by a dominant genetic mutation (Table 43.1). While accounting for at most 1–2% of all cases, these have been very informative. Three genes are known to carry these mutations. One is the APP itself (Goate et al., 1991). Mutations in APP which modify its cleavage to favor either more A β or longer forms of A β (A β ending at amino acid 42 instead of amino acid 40) can cause an early onset form of Alzheimer's, with symptoms beginning in the 40s to 50s. A second gene that can carry a large number of different mutations and cause Alzheimer's disease is referred to as presenilin-1 (Sherrington et al., 1995). All tested mutations in this gene that cause Alzheimer's disease increase production of the long form of A β . Presenilin-1 is a component of the complex that cleaves the variable C terminal of A β . It is also relevant that an extra gene dosage of APP can cause plaque and tangle pathology. A third gene accounting for a small portion of cases is presenilin-2. Most Down's syndrome carriers have an extra copy of the APP gene located on human chromosome 21. By age 40, most will have plaque and tangle pathology upon autopsy, and many will develop a dementia condition in their late 40s and 50s.

A second genetic category includes normally occurring polymorphisms that increase the risk of developing the disease. While many polymorphisms have been mentioned, one that is consistently linked to increased risk is the Apolipoprotein E4 allele. Individuals carrying this allele have a 3-fold greater risk of developing the disorder (Corder et al., 1993; Poirier et al., 1993). One effect of this allele is to lower the age of onset, so these cases are often found in the 60s. The third category is comprised of those cases for which genetic linkage cannot be identified. It is important to note that the extreme age of onset complicates genetic analyses, as the likelihood of forebears reaching the typical age of onset is quite low. Thus, the size of the idiopathic group is not well defined. As more gene polymorphisms become consistently linked to increased risk, the size of this population may decline.

The recognition that the final common path for all known genetic causes of Alzheimer’s disease, including Down’s syndrome, is increased amounts of the longer Aβ variants led to the development of transgenic mice over-expressing mutated forms of human APP. While many unsuccessful mice were generated in the early 1990s, the first to demonstrate compacted amyloid plaques was the PDAPP mouse (Games et al., 1995). Shortly thereafter, a second APP mouse, the Tg2576, was found to have remarkably similar pathology (Hsiao et al., 1996). In the same month, a presenilin transgenic mouse developed at the University of South Florida was described (Duff et al., 1996). Although the presenilin transgenic mice alone had little pathology, our group found that the presenilin mutation greatly accelerated the accumulation of plaque pathology when crossed with the Tg2576 mouse (Holcomb et al., 1998).

There are now a variety of different APP transgenic mice that develop plaque pathology. The similarities are, in the opinion of these writers, more striking than their differences. All develop compacted plaques in the cerebral cortex and hippocampus. These plaques are associated with dystrophic neurites and the activation of astrocytes and microglial cells. All mice develop a memory dysfunction that is usually correlated with Aβ levels in mice of a given age (Morgan, 2003). In none of the mice is there extensive neuron loss, as found in AD. Moreover, none of these mice develop tau pathologies, such as neurofibrillary tangles. Thus, these mice should be characterized as being models of amyloid deposition, not models of Alzheimer’s disease.

When Aβ is added to tau transgenic mice, the results suggest that amyloid pathology may precipitate tau pathology. Either when APP mice are crossed with tau mice (Lewis et al., 2001) or exogenous Aβ is applied to tau transgenic mouse brain (Gotz et al., 2001), there is acceleration of the tau pathology. Recently, a triple transgenic mouse has been generated that harbors APP, presenilin and tau mutations (Oddo et al., 2003), although neuron loss has not been reported to date. These transgenic models of select aspects of Alzheimer pathology have proven useful for preclinical evaluation of experimental therapies, which might be able to slow or halt the progression of Alzheimer’s disease, including immunotherapy.

43.2. Early Studies

The first suggestions that anti-Aβ antibodies may be useful in ameliorating amyloid pathology came from work by Beka Solomon and colleagues in Israel. They published that anti-Aβ antibodies could block the formation of Aβ fibrils from monomeric forms in vitro (Solomon et al., 1996). They then proceeded to show that these antibodies could disaggregate preformed amyloid fibrils, and that the antibodies could achieve disaggregation at stoichiometries less than 1:1 (Solomon et al., 1997). This suggested that the antibodies were catalytically dissolving the fibrils, presumably by favoring the formation of non-beta sheet conformations. Inclusion of antibodies could block the in vitro neurotoxicity of Aβ. Subsequently, they identified a

4 amino acid sequence in the N terminal domain of Aβ they felt was the essential epitope for this mode of action (Frenkel et al., 1998). The catalytic disaggregation hypothesis remains one of the major proposed mechanisms for the action of anti-Aβ antibodies (Table 43.2).

The first observation that vaccination against Aβ might effectively lower Aβ deposition in vivo came from Schenk et al. (1999). These authors demonstrated that immunization of young PDAPP transgenic mice resulted in dramatic reduction in amyloid deposition as the mice aged. Even when started at midlife, the immunization protocol eliminated formation of amyloid deposits. Importantly, they observed the presence of activated microglia in the vicinity of the few remaining deposits. This led them to speculate that opsonization of the amyloid deposits led the microglia to phagocytose this material.

The same group subsequently demonstrated antibody-stimulated phagocytosis could occur in vitro (Bard et al., 2000). They placed microglia on sections of Alzheimer disease brain tissue, with and without anti-Aβ antibody present. Only in the cases where the antibody was present did they observe clearance of the amyloid deposits by the microglia. Although cultured primary microglia and cell lines phagocytose fibrillar Aβ added to cultures, antibody addition accelerates this process (Webster et al., 2001). Thus, a second mechanism by which anti-Aβ antibodies may clear amyloid deposits is by microglial activation and stimulation of phagocytosis (Table 43.2).

A third mechanism by which antibodies might reduce brain Aβ levels was suggested by DeMattos et al. (2001). These authors noted that passive administration of a monoclonal antibody generated against Aβ resulted in large increases in circulating Aβ, analyzed by ELISA (a measurement that may be complicated by circulating antibody under some circumstances). They suggested that the circulating antibodies would sequester Aβ in the periphery, thereby increasing the brain to blood concentration gradient leading to a greater net efflux of Aβ from the brain to the periphery. It is important to recognize that the deposition of Aβ in mouse brain requires considerable over-expression of the APP transgene, always with a mutation that further increases the production of longer forms of Aβ. Thus it is conceivable that even minor shifts in the production and clearance of Aβ may have profound impacts on whether deposits accumulate or not.

TABLE 43.2. Mechanisms of anti-Aβ action.

Peripheral sink	Circulating anti-Aβ antibodies bind Aβ and reduce the free concentration in blood. This leads to increased net efflux from the brain	DeMattos et al. (2001)

For the most part, early studies of A β vaccination focused upon amyloid deposition. However, some of the APP mice were also being characterized behaviorally, and were found to have deficits in memory function that correlated with the extent of amyloid deposition (reviewed in Morgan, 2003). Thus, shortly after the publication that amyloid vaccination effectively reduced amyloid loads, our group and that of St-George-Hyslop et al began immunizing APP transgenic mice to observe the impact on memory formation. To be honest, our group was concerned that the vaccine might provoke excessive inflammation in the brains of the transgenic mice (by over-activating microglia), and cause premature memory deficits. This was based on a widely-held belief that inflammation associated with amyloid deposits may be a pathogenic mechanism in Alzheimer's disease (Akiyama et al., 2000). However, our testing specifically failed to identify premature memory loss with the immunization, and instead found protection from the development of memory deficits as the mice aged. Similar protection was found by the St-George-Hyslop group in the CRND8 APP transgenic mouse, and we arranged for tandem publication of these results (Morgan et al., 2000; Janus et al., 2000). Subsequent work found that some types of memory deficits could be reversed quite rapidly using passive immunization (Dodart et al., 2002; Kotilinek et al., 2002). This has led to the hypothesis that some pool of A β other than fibrillar deposits is responsible for some of the memory deficits observed in transgenic mice, and that this pool can be rapidly depleted by some anti-A β antibodies. Recent studies suggest that it is an oligomeric pool that is responsible for disruption of synaptic plasticity (Walsh et al., 2002; Cleary et al., 2005). Anti-A β antibodies appear capable of neutralizing the plasticity-disrupting influence of these oligomers (Klyubin et al., 2005).

It is not certain which of the proposed mechanisms of anti-A β immunotherapy is most correct. It is important to recognize that they are not mutually exclusive, and that all three may be working. In fact, the balance among these three mechanisms may vary for different types of immunotherapy.

43.3. Clinical Trial Experience with A β Vaccination

Based on the success of the A β vaccination approach in mouse models of amyloid deposition, Elan and Wyeth teamed to perform phase 1 and phase 2A trials in humans. Phase 1 trials resulted in no overt adverse events in human volunteers. Thus, a phase 2 trial was initiated with 300 patients receiving a vaccine against A β (AN1792; using QS-21 as an adjuvant) and 60 patients receiving placebo inoculations. The original goal of the trial was to repeatedly vaccinate patients until a predetermined anti-A β antibody titer was reached. It was noted in the phase 1 trial that only a portion of the patients developed measurable antibody titers against A β (Schenk, 2002). Even in the mouse

studies, repeated inoculation was necessary to achieve high antibody titers (Dickey et al., 2001a). This was further complicated by the advanced age of the patient population, which is known to cause increased variation in the response to vaccines.

Within several months of initiating the trial, the trial was interrupted due to the occurrence of multiple instances of adverse reactions in the patient population. This was characterized as aseptic meningoencephalitis, essentially swelling in the brain that was a form of autoimmune reaction presumably elicited by the vaccine (Orgogozo et al., 2003). Examination of tissue from two patients who ultimately came to autopsy revealed substantial T cell infiltration into the brain (Nicoll et al., 2003; Ferrer et al., 2004). In all, roughly 6% of the patients in the trial developed these symptoms, with the majority recovering after treatment with steroidal anti-inflammatory agents.

Although the inoculations with the A β vaccines were discontinued, the patients in the trial continued to be monitored both medically and cognitively. One cohort of patients in the trial, those in Zurich, appeared to have benefited from the vaccine. Hock et al. (2003) found that those patients with the highest antibody titers appeared to remain stable cognitively. This stabilization appeared to extend 2 years after the last immunization. Importantly, it was the titers of antibodies that reacted with the amyloid deposits on brain sections that were associated with cognitive benefits (Hock et al., 2002). ELISA assayable titers did not associate with improved behavioral outcomes. When the entire study was analyzed, the linkage between antibody titers and cognitive benefit was less substantial (Gilman et al., 2005). It is unclear whether measurement of brain reactive antibody titers would improve this association as found for the Zurich cohort. Important caveats regarding the implications of this study stem from its truncation. Any results have to be considered within the context that the trial was not completed as planned and the potential benefits or failures must be considered in this context.

The histopathology of the patients in this trial is limited to three published reports. Two from patients that had a meningoencephalitic reaction (Nicoll et al., 2003; Ferrer et al., 2004) and one from a patient lacking any adverse reaction to the vaccine (Masliah et al., 2005). Although control cases were archival and the number of cases is very small, all three reports suggest there was less amyloid deposition than would be expected for an AD patient at each patient's stage of the disease. The reductions did not appear uniform throughout the brain. Moreover, the reductions appeared to be primarily in the neuritic plaque and diffuse A β deposits, but not in the amyloid deposits associated with the blood vessels.

A curious observation in the trial was the MRI findings of increased hippocampal shrinkage in those patients with the highest antibody titers (Fox et al., 2005). This occurred over the first year of the trial, and was also accompanied by ventricular enlargement. A similar observation was made within the Zurich cohort; however in this case, by the end of the second year, the hippocampal volumes were greater in those patients with the highest brain reactive antibody titers (Nitsch, 2004). Nitsch has

speculated that the initial loss of brain volume is secondary to two major changes; elimination of the bulk of the accumulated A β peptide and reduction of the inflammation and edema associated with the glial reaction to the amyloid deposits. It remains to be seen if the apparent stabilization of brain volume occurs in year 2 for the entire cohort of the clinical trial.

43.4. Other Forms of Active Immunization

Certainly, the AN1792 vaccine developed by Elan was relatively simple. It consisted of full length A β peptide, incubated in a physiological salt solution to promote fibril formation injected with a QS-21 adjuvant. One of the major issues in developing an effective A β vaccine is the recognition that A β is a self-protein to some extent. A β may be present in normal cells, albeit as a minor and short-lived product of APP processing. Thus vaccines may need to break self-tolerance (Monson et al., 2001). A second consideration is that an autoimmune reaction may have undesirable effects, such as that observed in those patients developing meningoencephalitis in the AN1792 trial. Presumably, these adverse reactions were due to development of a T cell response against A β , a self-antigen. A third consideration is that the relatively short A β peptide is not by itself a very potent immunogen. Thus, since the original publication by Schenk et al. (1999), there have been a number of alternative vaccine formulations investigated to produce anti-A β antibodies.

One of the first was an attempt to use mucosal vaccination as an alternative to injections (Weiner et al., 2000; Lemere et al., 2002). This was found to be an effective approach with both production of high titer antibodies and clearance of amyloid deposits in transgenic mice. Another approach was to use a liposome-based therapy with the A β 1–16 peptide rather than full-length molecules (Nicolau et al., 2002). This palmitoylated vaccine construct was effective in breaking down self-tolerance to the vaccine in A β -overproducing mice. A different rationale was developed by a group at New York University (Sigurdsson et al., 2002). They were concerned that injecting full-length A β , a known neurotoxin, could produce adverse reactions by forming fibrils. This group has explored use of a truncated and modified A β peptide, which retains immunogenicity but not the capacity to form fibrils. Importantly, this vaccine can also reverse memory deficits in transgenic mice (Sigurdsson et al., 2004).

Another series of vaccines have used genetic engineering to produce a B-cell epitope towards A β and a T-cell response towards a non-self antigen. Agadjanyan et al. (2005) used the first 15 amino acids of A β (where the vast majority of vaccine-generated antibodies bind; (Dickey et al., 2001b; McLaurin et al., 2002) coupled to a synthetic universal T cell epitope (PADRE). This succeeded in producing an immune response with high anti-A β antibody titers, but with no splenic T cell activation against the A β peptide. Presumably, a vaccine with these properties would not result in the autoimmune T cell reaction and would avoid the meningoencephalitic reaction

found in some patients in the AN1792 trial. Importantly, these same authors found that the adjuvant chosen for the AN1792 trial, QS-21, biased the immune response toward a Th1 type of reaction (Cribbs et al., 2003). Given that Th1 responses are associated with autoimmune reactions, while Th2 responses suppress autoimmune responses, the choice of adjuvant may have contributed to the adverse events that were found with the active vaccine trial.

Another approach has been the development of DNA-based vaccines, where A β or a component is encoded genetically. Several of these have used viral vectors to deliver the vaccine. Hara et al. (2004) administered adeno-associated virus encoding the A β peptide orally to mice. This resulted in epithelial cell expression of A β and prolonged elevation of anti-A β antibody titers, without eliciting T cell responses against A β . Kim et al. (2004) used an adenovirus vector encoding A β plus an adenovirus vector encoding GM-CSF to produce an immune response after intranasal administration. This response was found to have a Th2 bias, and was effective in reducing A β content in the brains of APP transgenic mice. Lavie et al. (2004) used a filamentous phage vector displaying only 4 amino acids from A β (EFRH; aa3–6). This vaccine produced a humoral response against A β , reduced brain amyloid loads and protected APP mice from cognitive deficits. Interestingly, another approach using an HSV amplicon to drive A β expression with a tetanus toxin fragment produced CNS inflammation, and may serve as a model for the autoimmune reaction apparently found in the AN1792 trial (Bowers et al., 2005).

Thus, there have been a number of clever alternative approaches to developing active immunization protocols for the possible treatment of Alzheimer's disease. Most either enhance the immunogenicity of the vaccination regimen, reduce the possible autoimmunity or both. Nonetheless, there are still potential problems with all of the vaccines. For example, the response will be variable in an aged population, as was clearly found for the AN1792 trial (Bayer et al., 2005). A second consideration is the epitope specificity of the humoral response. Antibodies directed against one epitope may be more effective than others (for example, the apparently greater effectiveness of antibodies reacting with brain amyloid deposits; (Hock et al., 2003). A final consideration is that it is still not certain why the patients developed the meningoencephalitic reaction in the first place. Certainly, the argument that T cell activation against a self-antigen elicited an autoimmune reaction appears logical, but this is not at all proven. There is no good mouse model of the type of reaction found in the two human cases that have come to autopsy (the report by Furlan et al., 2003, has been difficult to replicate). Active immunization reactions can be difficult to control; one cannot unvaccinate someone after the plunger has gone down. Still, if anti-A β immunotherapy does prove effective in halting or even slowing the progression of Alzheimer's dementia, it is likely that active immunization regimens will become a critical component to therapy for this disease, if only because of their reduced costs compared to passive immunization approaches.

43.5. Passive Immunization

The use of monoclonal antibodies as therapeutics has become commonplace. Antibodies or chimeric proteins against TNF- α are very effective in quelling certain inflammatory diseases. Trastuzumab (against HER2) is effective in reversing the growth of some breast tumors. As of 2005, there were 15 antibody therapeutics approved for use in the US.

Monoclonal antibodies against A β appear equally effective in reducing brain amyloid deposits as active immunization against A β . Bard et al. (2000) were the first to demonstrate that systemic administration of anti-A β antibodies can lower amyloid loads. Importantly, they found that not all antibodies were equally effective in reducing brain A β content (Bard et al., 2003). In a striking demonstration that amyloid plaques are rapidly reversible structures in transgenic mouse brain, Bacskai et al. (2001) found that amyloid deposits imaged through a craniotomy window with multiphoton microscopy could be removed within 3 days after topical administration of an anti-A β antibody. Injections of anti-A β antibodies directly into the brain parenchyma caused a time-dependent clearance of A β deposits over a period of a week (Wilcock et al., 2003). Similar effects of monoclonal antibodies were found after intraventricular administration (Chauhan and Siegel, 2002; Chauhan and Siegel, 2003). In the triple transgenic mouse model, Oddo et al. (2004) found that antiA β antibody injections into the hippocampus not only cleared amyloid deposits, but also reduced the hyperphosphorylation of tau at some sites. Intriguingly, after 45 days, the amyloid deposits returned as did the tau hyperphosphorylation.

In an attempt to model conditions more proximal to those found in Alzheimer patients, our research group started a passive immunization study in older (19 mo) Tg2576 mice (roughly equivalent to a 65-year-old human with respect to total lifespan). These mice already had considerable plaque accumulation at this age. A time course of the passive immunization therapy (weekly injections) found an initial activation of microglial cells detected by increased expression of Fc γ -receptors and CD45 (Wilcock et al., 2004a). By 2 months, there were reductions in both diffuse and fibrillar forms of A β , which continued out to three months. By this time the fibrillar amyloid plaques found in the parenchyma were 90% lower in the mice treated with anti-A β antibodies than in mice given control injections. We also found substantial elevations in circulating A β levels. By 3 months (but not 1.5 months), these mice also displayed improved cognitive performance. However, in this study and a second study using 5 mo of passive immunotherapy, we observed an increase in vascular amyloid deposits, essentially a murine form of cerebral amyloid angiopathy (Wilcock et al., 2004b). Although this surprised us, an earlier paper found that passive immunization of a different APP mouse, the APP23 mouse, caused an increase in microhemorrhage (Pfeifer et al., 2002). Upon testing in these mice, we confirmed the increase in microhemorrhage as well. However, in spite of this vascular leakage, the learning and memory performance of these old transgenic mice was indistinguishable from nontransgenic mice, and dramatically better

than control transgenic animals. A similar observation of increased hemorrhage in mice passively immunized with one antibody, but not another, was reported in parallel by Racke et al. (2005).

It is not entirely clear why some antibodies result in vascular leakage and others do not. It may be that one of the proposed mechanisms of antibody action (microglial activation, for example) predisposes towards this result. Antibodies which do not result in microglial activation may not redistribute amyloid from the parenchyma to the vessels, or result in microhemorrhage. It is also important to recognize that microhemorrhage does not occur in younger mice (Pfeifer et al., 2002). Either the young mice have insufficient amyloid to liberate, or the younger vessels are less sensitive to the weakening caused by cerebral amyloid angiopathy. Nonetheless, it is of some concern that none of the three autopsy studies find reduction in cerebral amyloid angiopathy (in fact it is rated as being high) and one (Ferrer et al., 2004) notes that there is hemorrhage in association with some vascular plaques in this patient.

Within the passive immunization field, there have been discussions of antibody superiority based upon the epitope domain of the antibody (usually divided into N terminal, mid domain or C terminal) or the antibody subtype (IgG1, IgG2a, IgG2b etc), with the conclusion that one type of epitope specificity or subtype is better than another. A third consideration is antibody affinity for A β . Unfortunately, none of these features has been manipulated independent of the others. Each individual antibody will vary in all of these properties, and, particularly for epitope specificity, it is very difficult to assume equivalence. Thus far, in the opinion of this author, each antibody needs to be considered a separate entity. Each antibody's ability to clear amyloid *in vivo*, inactivate oligomers, activate microglia, bind A β , increase circulating A β and activate effector molecules (such as Fc γ -receptors) must be measured directly. It is plausible that some antibodies may have superior profiles in clinical trials because of one or more of these properties. However, assuming that it is one of these properties, which confer superiority without measuring them, all will likely be misleading.

43.6. Circulating Antibodies

Several groups have found that some individuals have titers of antibodies against the A β peptide. Unfortunately, consensus regarding a relationship to Alzheimer's disease has not yet emerged as there are reports of increased titers with disease (Nath et al., 2003), decreased titers with disease (Weksler et al., 2002) or no effect of disease (Hyman et al., 2001). It should be noted that the antibody titers observed are extremely low compared to those observed after immunization. Moreover, it is not clear the degree to which endogenous A β may interfere with the detection of anti-A β antibodies by ELISA (see Li et al., 2004).

Still, this has led to a short, open label trial of human intravenous immunoglobulin, an FDA approved product that has benefit in several types of disorders, including multiple sclerosis. Dodel et al. (2004) reported that

monthly administration of intravenous immunoglobulin to 5 Alzheimer patients reduced A β in cerebrospinal fluid, increased A β in serum and improved cognition. Although a definitive conclusion awaits a clinical trial, it is surprising that such a treatment would be effective, even at the large doses administered, because of the vanishingly small amounts of anti-A β antibodies present. Instead, if confirmed in a larger controlled trial, this observation may suggest a fourth mechanism by which immunotherapy might benefit Alzheimer patients: by modulation of the immune response. One feature of immunoglobulin therapy is that the circulating levels of IgG increase dramatically. This results in feedback regulation of a number of immune processes, as the levels gradually return towards normal. This may also explain the rather curious finding that administration of a proteosome adjuvant with glatiramer acetate alone is adequate to reduce amyloid deposits in transgenic mice (Frenkel et al, 2005). This does not require the presence of antibodies, and appears related to the activation of resident microglial cells near the amyloid deposits. Thus, it is conceivable that immunomodulation may be just as important as a specific immune reaction in the benefits of immunotherapy in APP transgenic mice. Clearly it will be critical to identify if the same holds in human trials.

Summary

Alzheimer's disease is a progressive neurodegenerative disorder in which memory and cognitive dysfunctions are the earliest symptoms. Pathologically, the disorder is characterized by neuron loss in hippocampus and multiple cortical regions, along with the formation of extracellular amyloid plaques and intracellular neurofibrillary tangles. The amyloid in this disorder is comprised largely of a peptide called A β , which is a degradation product of a protein with unknown function referred to as the amyloid precursor protein. The genetics of dominant inherited forms of Alzheimer's disease implicate increased production of the long form of the A β peptide as the critical feature leading to unavoidable development of the disease. This recognition has led many to consider anti-amyloid therapeutics as a means of slowing or arresting the disease. One approach that may become the first to test the so-called "amyloid hypothesis" is immunotherapy. Both vaccination and monoclonal antibody therapies have been tested with considerable success in mouse models of amyloid deposition. These approaches can prevent the formation of amyloid deposits, remove already existing deposits, and reverse the memory deficits associated with amyloid deposition in these mice. A human clinical trial was cut short due to an apparent autoimmune reaction in a fraction of the patients, but the results from this truncated trial still suggest that there may be therapeutic benefits of the approach. Current research is focusing on trying to understand the mechanisms by which antibodies directed against A β aid in clearing the amyloid deposits, how the vaccines might be constructed to overcome self-tolerance without evoking

autoimmune reactions, and testing various monoclonal antibody preparations for efficacy in clinical trials. Even partial success in slowing the progression of this disease can have considerable societal and economic impact. Furthermore, verification of the amyloid hypothesis will encourage development of a number of other anti-amyloid therapies that may synergize with the immunotherapeutic approach.

44.1. Introduction

Parkinson's Disease (PD) and Amyotrophic Lateral Sclerosis (ALS) are common neurodegenerative disorders in the aging population. The primary pathological characteristics of PD are the progressive loss of dopaminergic neurons in the substantia nigra pars compacta (SNpc) and reductions in their termini within the dorsal striatum (see Przedborski, Chapter 26). These lead to profound and irreversible striatal dopamine loss. Cell modeling data indicate that 100–200 SNpc neurons degenerate per day during PD (Orr et al., 2002). ALS, also known as Lou Gehrig's disease, is characterized by gradual degeneration of spinal cord motor neurons eventually leading to progressive weakness, paralysis of muscle, and death (see Simpson et al., Chapter 27). The mechanisms for neurodegeneration in both disorders relate, in part, to the abnormal accumulation, oligomer formation and misfolding of α -synuclein for PD and superoxide dismutase 1 (SOD1) for ALS. These protein aggregates form at synapses and axons leading to signaling abnormalities and neuronal dysfunction. Neuroinflammatory responses, mitochondrial function, glutamate transport toxicity, and free radicals formulation are linked as a consequence of protein toxicities and lead to neuronal destruction in both disorders. It is hypothesized, all together, that changes in the balance between factors promoting aggregation, clearance and synthesis of α -synuclein and SOD1 is a central component of disease pathogenesis. Microglial activation and alterations in lysosomal function are linked to oligomer accumulation. These can accumulate in the membrane and can be recognized by antibodies that promote their clearance (Masliah et al., 2005). Antibodies can lead to decreased accumulation of aggregated α -synuclein in neuronal cell bodies and synapses associated with reduced neurodegeneration. Antibodies can also recognize abnormal α -synuclein associated with the

neuronal membrane and promote their degradation through lysosomal-autophagy pathways. Thus, vaccination is effective in reducing the neuronal accumulation of α -synuclein aggregates and further development of this approach might have a potential role in the treatment of PD (Miller and Messer, 2005). Such an anti-amyloidogenic property might also provide a novel strategy for the treatment of other neurodegenerative disorders. Antibodies specific for peptides or conformations of misfolding neurodegenerative disease proteins can be engineered for affinity and stability; and then delivered intracellularly as intrabodies. For SOD1-linked familial ALS, aberrant oligomerization of SOD1 mutant proteins has been implicated. Formation of soluble oligomers suggests a general, unifying picture of SOD1 aggregation linked to neuronal destruction. Thus, vaccination with α -synuclein or SOD1 has been proposed for treatment of disease. In the case of ALS, vaccination with recombinant SOD1 or passive immunization with antibodies against SOD1 species has been tested with success in mouse models of ALS. These parallel similar successes in rodent models of PD. This therapeutic approach is based on reduction of toxic mutant proteins. However, caution is noted in developing such approaches. Work from our own laboratory has shown the importance of the cell-mediated adaptive immune system in neuroprotective treatment strategies for PD and ALS. In particular, T cells have beneficial and harmful affects on neurodegenerative processes. Immunoregulatory treatments [e.g., glatiramer acetate (GA), vasoactive intestinal peptide (VIP), granulocyte macrophage-colony stimulating factor (GM-CSF), and 1,25-dihydroxyvitamin D3] that modulate T cell responses can play an important role in future immunotherapies. In this chapter we review the roles of the innate and adaptive immune system in the pathogenesis of PD and ALS and the recently developed means to harness both for therapeutic benefit (Figure 44.1).

New modalities in genomics, proteomics, and imaging have allowed monitoring of these effects and provide new directives for the future. All together, we provide a balanced review for the role of immunity in the pathogenesis of PD and ALS and the means to modulate it for therapeutic benefit. The strengths and concerns for each of these approaches are discussed.

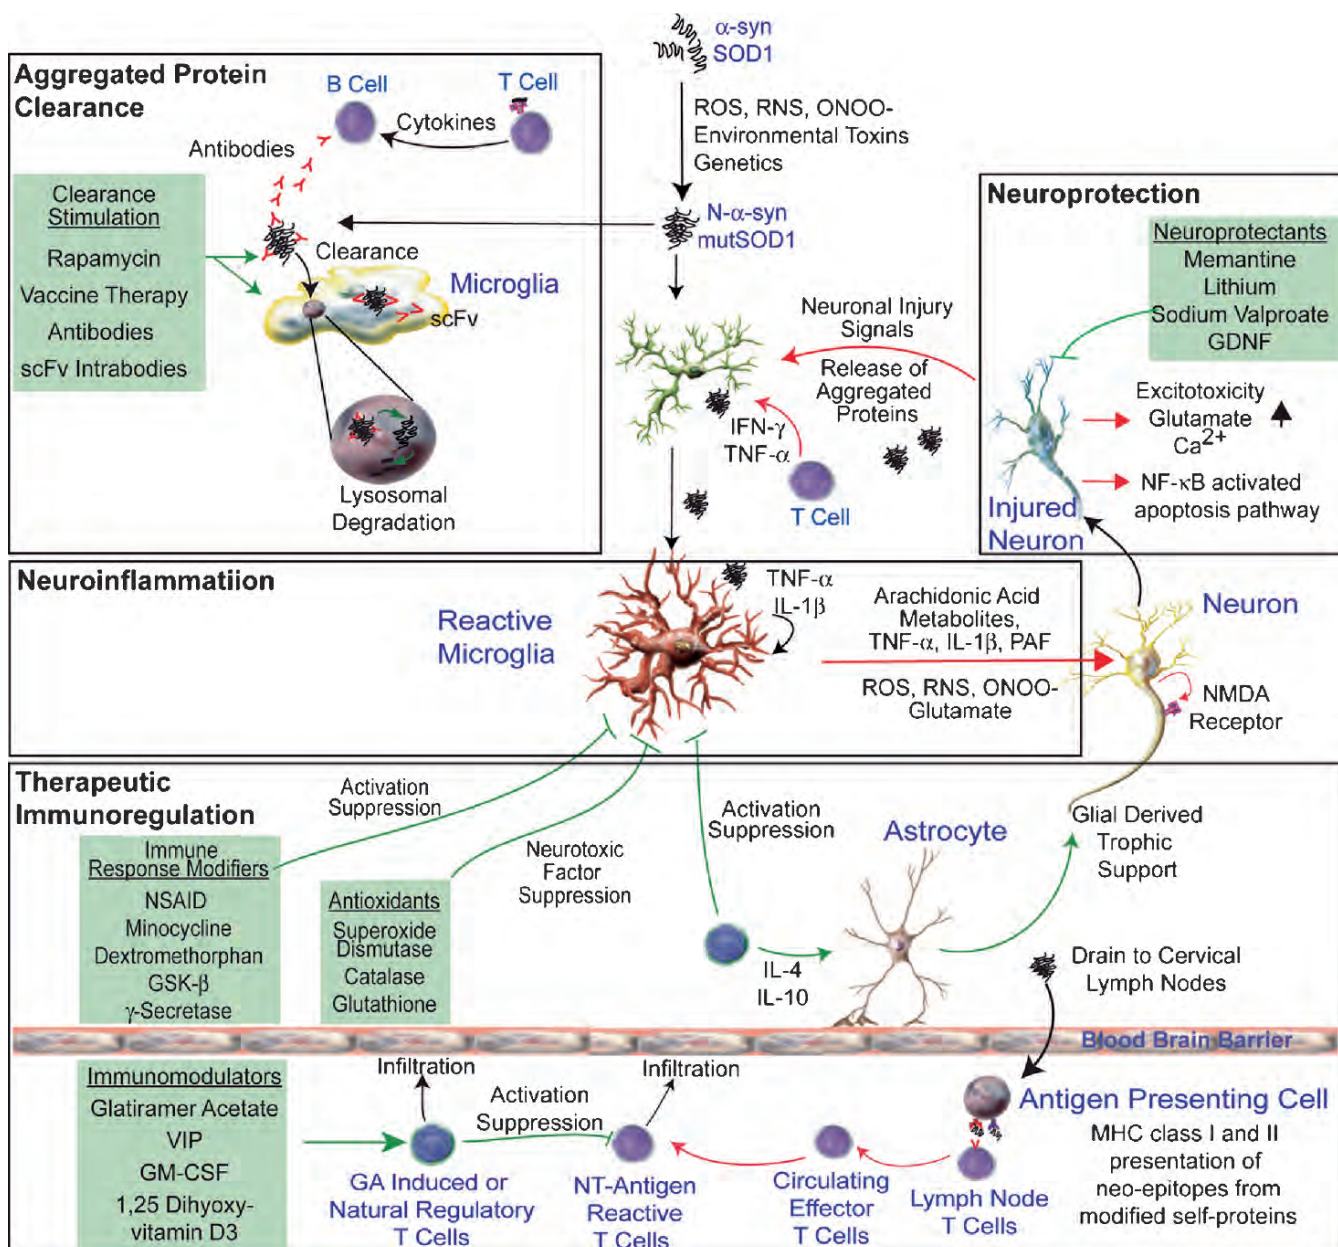

FIGURE 44.1. Immunotherapeutic strategies for PD and ALS. There are several different targeted approaches currently available, or that can be imagined for the treatment of PD or ALS. The first of these is targeting the aggregated or misfolded proteins themselves to prevent oligomer-induced microglial activation. Vaccine-induced antibodies or intracellular-produced single chain antibodies (scFv, intrabodies) directed against misfolded/aggregated proteins, or drugs (e.g., rapamycin) that stimulate microglial/macrophage phagocytosis and lysosomal degradation may prove of therapeutic benefit by clearance of extracellular or intracellular misfolded/aggregated proteins. Another approach may use drugs that directly inhibit neurotoxicity (e.g., by inhibiting excitotoxicity or apoptosis) or promote neuroprotection (e.g., glial cell line-derived neurotrophic factor, GDNF), thus slowing disease progression. Finally, significant efforts are being made towards modulation of the immune response to misfolded/aggregated proteins. This may be accomplished by use of immune response modifiers and antioxidants that attenuate microglial activation. With the realization that disease can either be exacerbated by effector T cells specific for neo-epitopes from modified self-CNS proteins (e.g., NT-modified proteins) or be ameliorated by regulatory T cells (natural or antigen-induced), therapeutic immunoregulation by immunomodulators or adjuvants to induce or upregulate regulatory T cell responses can inhibit exacerbated adaptive and innate immune responses and interdict further neurodegeneration. α -syn, α -synuclein; GA, glatiramer acetate; GM-CSF, granulocyte macrophage colony stimulating factor; GSK3- β , glycogen synthase kinase 3- β ; IFN- γ , interferon- γ ; MHC, major histocompatibility complex molecule; mutSOD1, mutant superoxide dismutase-1; N- α -syn, nitrated α -synuclein; NMDA, N-methyl-D-aspartic acid; NSAID, nonsteroidal anti-inflammatory drugs; NT, nitrotyrosine; ONOO-, peroxynitrite; PAF, platelet-activating factor; RNS, reactive nitrogen species; ROS, reactive oxygen species; SOD1, superoxide dismutase-1; TNF- α , tumor necrosis factor- α ; VIP, vasoactive intestinal peptide.

44.2. Protein Misfolding and Modifications

44.2.1. α -Synuclein and SOD1 Biology and Biochemistry

α -Synuclein is a major constituent protein in Lewy bodies for which expression of several mutations, duplication or triplication in genes encoding for α -synuclein induce early-onset PD (Polymeropoulos et al., 1997; Kruger et al., 1998; Singleton et al., 2003; Chartier-Harlin et al., 2004; Farrer et al., 2004; Ibanez et al., 2004). Misfolding of this protein and lack of clearance is thought to play a major role in progression of PD. Two major cellular mechanisms of clearance include degradation by the ubiquitin-proteasome and the autophagic-lysosomal pathways. The former is supported by mutations in PD patients for *PARK2* (Waters and Miller, 1994) and *PARK5* (Liu et al., 2002) which respectively encode for proteins with ubiquitin E3 ligase and ubiquitin C-terminal hydrolase activities. The latter mechanism is supported in α -synuclein over-expressing cells by the presence of α -synuclein in organelles with morphological features of autophagic vesicles, increased clearance of α -synuclein with rapamycin, an autophagy stimulator, and increased accumulation of aggregated α -synuclein when this pathway is blocked (Webb et al., 2003; Lee et al., 2004). Moreover, clearance seemingly occurs in an aggregation stage-specific manner where the more toxic oligomeric intermediates are susceptible to clearance, but mature fibrillar inclusion bodies are not. Neutralization of the acidic compartments leads to the accumulation of α -synuclein aggregates and exacerbates α -synuclein-mediated toxicity and cell death (Lee et al., 2004). In ALS, SOD1-positive aggregates are observed in the spinal cords from autopsied familial ALS (FALS) patients, as well as, from mutant SOD1 (mutSOD1) transgenic mice and are thought to play a role in toxicity and neuronal cell death (Shibata et al., 1996; Bruijn et al., 1997; Watanabe et al., 2001; Puttaparthi et al., 2003; Kabashi and Durham, 2006). Clearance of SOD1 aggregates involves proteasome activity, as inhibition of proteasome-mediated proteolysis promotes SOD1 aggregation in tissues from G93A SOD1 mice, whereas restoration of activity reverses aggregate formation (Puttaparthi et al., 2003). However, whether SOD1 impairs proteasomic activity is unclear as analyses from several laboratories yielded mixed results of unchanged, increased, or decreased proteolytic activities measured in mutant SOD1 mice (Kabashi and Durham, 2006). Of interest, proteasomal proteolytic activity in the cytoplasm, but not in the nucleus has been shown to be impaired from motor neurons of SOD1 mice. Additionally, clearance of mutant SOD1 by autophagy is comparable to that of the proteasome pathway as shown under conditions where mutant SOD1 is not toxic, the inhibition of macroautophagy induces mutant SOD1-mediated aggregation and cell death (Kabuta et al., 2006). Thus enhancing proteosomal or lysosomal function may be potential therapeutic

strategies to halt disease progression in those afflictions associated with aggregation of misfolded proteins (Figure 44.1).

44.2.2. Protein Nitration

Postmortem analyses of PD patients have consistently demonstrated the increased presence of nitrated residues as biomarkers for oxidative stress. Protein modifications are among the many biomarkers detected in the brains of PD patients. Compared to brains from control donors, elevated levels of nitrated proteins are found in brains and CSF of PD patients (Aoyama et al., 2000). Most notable are 3-nitrotyrosine (NT) modifications of proteins that comprise Lewy bodies (LB), the neuronal inclusions that are considered the hallmarks of PD and consist primarily of α -synuclein, ubiquitin, and lipids (Duda et al., 2000; Giasson et al., 2000) suggesting an increased participation of inflammatory responses and reactive molecular species; however, whether those modifications occur before or after inclusion into LB remain unclear. Also S-nitrosylated forms of parkin (*PARK2*) have been isolated from the temporal cortex from PD patients (Yao et al., 2004). Carbonyl modifications, which are reflective of protein oxidation, are increased in SN, basal ganglia, globus pallidus, substantia innominata, cerebellum and frontal pole compared to controls and patients with incidental LB disease (ILBD), a putatively presymptomatic PD disorder. Whether the involvement of the latter two regions reflects a consequence of L-DOPA treatment or a more global consequence of the inflammatory spread of oxidative stress in PD is unclear. However, increased expression of neural heme oxygenase-1 and glycosylated proteins by nigral neurons provides additional evidence for oxidative damage to proteins in PD.

In ALS, abundant evidence points to the effects of peroxynitrite in affected tissues. Significant increases in levels of NT moieties are detected on CSF proteins from ALS patients (Aoyama et al., 2000; Shaw and Williams, 2000), including Mn superoxide dismutase (Mn-SOD) which is only slightly increased in patients with AD and PD (Chou et al., 1996; Aoyama et al., 2000). Moreover, NT immunoreactivity is associated with motor neurons of the spinal cord and axons (Calingasan et al., 2005), and co-localizes to axonal conglomerates and spheroid neurofilament accumulations of upper and lower motor neurons (Chou et al., 1996) and with A β -40 depositions within abnormal neurons (Calingasan et al., 2005).

44.3. Microglial Inflammatory Responses and Therapies

44.3.1. Innate Immunity and Disease

PD is characterized by activation of microglial cells found in and around degenerating neurons. Reactive microglia are commonly seen within the SNpc of PD brains investigated at

autopsy (Croisier et al., 2005). A six-fold increase in numbers of reactive microglia has been shown phagocytosing dopaminergic neurons (McGeer et al., 1988b) and correlates with the deposition of α -synuclein (Croisier et al., 2005). These reactive microglia over-express HLA-DR of the human MHC II complex, complement receptor type 3 (CR3, CD11b/CD18, Mac-1, Mo 1), CD68 (EMB11), CD23 (Fc ϵ RII, Fc receptor II for IgE), ferritin, CD11a (lymphocyte function-associated antigen-1, LFA-1) and CD54 (ICAM-1). They also secrete a plethora of proinflammatory cytokines such as interferon- γ (IFN- γ) tumor necrosis factor- α (TNF- α), interleukin 1- β (IL-1 β), and upregulate enzymes such as inducible nitric oxide synthase (iNOS), and cyclooxygenase (COX) 1 and 2. MHC class II positive microglia also are increased in the putamen, hippocampus, transentorhinal cortex, cingulate cortex and temporal cortex of the PD brain. Reactive microglia serve as *in vivo* indicators of neuroinflammatory responses and contribute significantly to progressive degenerative processes. In early-stage PD imaging, PK11195 ligand binding to peripheral benzodiazepine receptors that are upregulated on reactive midbrain microglia and serve as markers of neuroinflammation, inversely correlates with binding of 2- β -carbomethoxy-3 β -(4-fluorophenyl) tropane (CFT) to the dopamine transporter (DAT) in the putamen as a measure of surviving dopaminergic termini and also correlates with the severity of motor impairment (Croisier et al., 2005). Additional evidence for the involvement of neuroinflammation includes epidemiological data that demonstrate daily nonsteroidal anti-inflammatory agents decrease the risk of PD in a large cohort (Chen et al., 2003; Chen et al., 2005). Biochemical and histological evidence in PD brains of increased levels of carbonyl and nitrotyrosine protein modifications, lipid peroxidation, DNA damage, and reduction of glutathione and ferritin, the end results of inflammatory processes, also support the importance of inflammation in PD (Hald and Lotharius, 2005). Postmortem samples of SNpc from sporadic PD patients show elevated levels of the protein gp91^{phox}, the main transmembrane component of NADPH-oxidase, which co-localize with microglia and are associated with the production of ROS. Likewise, in 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP)-treated mice (see Przedborski, Chapter 26), large increases in gp91^{phox} immunoreactivity also co-localize in the SNpc with activated (Mac-1 immunopositive) microglia, but not with astrocytes or neurons. Studies of post-mortem brains from three human subjects who, after 3–16 years previously had injected MPTP and developed parkinsonian syndromes, exhibited accumulations of activated microglial cells around dopaminergic neurons (Langston et al., 1999). Thus, an initial acute insult to dopaminergic neurons likely leads to a secondary and perpetuated neuroinflammatory response. This neuroinflammatory reaction serves to alter homeostatic neural mechanisms or exacerbate disease processes by production of proinflammatory factors (Figure 44.1).

In ALS patients an abundance of data indicates the active involvement of the immune system in disease processes. Activated

mononuclearphagocytic (MP; macrophages and perivascular microglia) cells are found in affected tissues in ALS patients (Graves et al., 2004; Henkel et al., 2004). Several postmortem studies of tissues from ALS patients exhibiting neuronal loss compared to those of controls demonstrate the increased presence of activated microglia in the ventral horn of the spinal cord, corticospinal tract, motor cortex, and brainstem (Henkel et al., 2004), and are thought to be involved in phagocytosis of degenerating neurons since they are found in close proximity in tissues showing early signs of degeneration. Macrophages and amoeboid microglia within those affected tissues from ALS patients exhibit upregulated HLA-A, -B, -C, and -DR molecules, Fc γ RI, CR3 (CD11b/CD18), CR4 (CD11c/CD18), macrophage-colony stimulating factor (M-CSF) receptor (CSF-1R), β 2 integrins, COX-2, iNOS, and CD40 receptor which strongly suggest those microglia are in a reactive state. Furthermore, *in vivo* PET imaging using PK11195 to visualize upregulated peripheral benzodiazepine receptor by activated microglia show increased levels in the motor cortex, dorsolateral prefrontal cortex, thalamus, and pons of ALS patients. Recent works in mutant SOD1 transgenic mice (see Simpson et al. Chapter 27) suggest a promising therapeutic strategy targeting the innate immune system. The presence of wild type cells in the wild type/SOD1 Tg mouse chimeras enhances survival, whereas mutant SOD1 acting within non-neurons was toxic, no matter whether chimeric construction was with embryonic cells or via bone marrow transplantation to irradiated recipients (Clement et al., 2003; Corti et al., 2004). To assess the role of SOD1 expression in MP cells on survival, mice transgenic for mutSOD1 and flanking LoxP sequences (LoxSOD1) were crossed with mice expressing Cre under control of the CD11b promoter, an integrin exclusively expressed by myeloid cells (Boillee et al., 2006). Those crosses exhibited diminished SOD1 expression in microglia and macrophages, but not other cells, and extended survival compared to LoxSOD1 controls. Although no discernible differences in the activation phenotype of microglia or macrophages could be demonstrated, SOD1 expression was significantly diminished. Finally, reconstitution of G93A-SOD1/PU.1^{-/-} mice with wild-type bone marrow cells, established donor-derived microglia within the CNS, slowed motoneuron loss, prolonged disease duration and survival compared to mice treated with bone marrow cells from SOD1 transgenic animals (Beers et al., 2006). Taken together, these data suggest that targeting innate immunity and expression of SOD1 in the CNS of ALS represent a plausible therapeutic modality for ALS (Figure 44.1).

44.3.2. Oxidative Stress

Once activated, microglia can produce noxious factors including pro-inflammatory cytokines, chemokines, quinolinic acid, arachidonic acid and its metabolites, and excitatory amino acids among others. A major defense mechanism provided by MP is the production of free radicals and reactive molecular

species, all potentially toxic to invading organisms. The cellular machinery of myeloid lineage cells that has evolved to produce these toxic products is NADPH oxidase (expressed by microglia, macrophages and neutrophils) and myeloperoxidase (expressed predominately by neutrophils). Among neurons, astrocytes and microglia of the CNS, microglia are,

in large measure, responsible for generating a major portion of free radicals (Figure 44.2) (Klegeris and McGeer, 2000).

Reactive species of oxygen, nitrogen, and carbon are thought to play an active role in PD and ALS wherein the very utilization and production of neurotransmitters produces harmful reactive species. In PD, the metabolism of

FIGURE 44.2. Neuroinflammatory and oxidative stress pathways in PD and ALS pathogenesis. Free radicals can arise several diverse ways, such as glial cell activation, mitochondrial dysfunction, and protein aggregation. Increased microglia activation is attributable to increased neuronal cell death and cell debris including aggregated proteins. In ALS and related-animal models, mutated SOD1 (mutSOD1) expression increases aggregated proteins, neuronal death and microglial activation. Microglial derived NO and superoxide ($\cdot\text{O}_2^-$) species react in extracellular spaces to form peroxynitrite (ONOO^-). Peroxynitrite readily crosses cell membranes where it contributes to lipid peroxidation, DNA damage and nitrotyrosine formation in α -synuclein and other cellular proteins. Damaged proteins are targeted to cellular proteasomes for degradation via the ubiquitination pathway. Excess NO produced by activated microglia can lead to S-nitrosylation of cellular proteins, including parkin. Such modifications may diminish E3 ubiquitin ligase activity necessary for efficient protein turnover by proteasomes. Excessive protein damage caused by oxidants and disruptions in the ubiquitin pathways may overload or inhibit protein degradation quality control measures leading to the accumulation of damaged proteins in cells. When reactive species exceed anti-oxidant defenses, oxidative stress is generated; destroying molecular structures, such as proteins, lipids and DNA, causing irreversible and detrimental damage, neuronal cell injury and death. Adapted from Gao et al. (Gao et al., 2003).

dopamine that produces H_2O_2 can exacerbate inflammation and tissue damage by feeding into the ROS cycle and/or by dopamine-quinone modification of protein sulfhydryl groups via nucleophilic additions. Glutamate signaling through the NMDA receptor involves the generation of a hydroxyl radical, the excess of which has been shown to be excitotoxic, while glutamate ligation of the kainite receptor has been shown to induce reactive oxygen and nitrogen species. However, production of the majority of reactive oxygen species is mediated through the superoxide radical produced by NADPH-oxidase; the inhibition of which mitigates neurodegeneration in numerous model systems including MPTP (Wu et al., 2003).

NO is a biological messenger molecule that has numerous physiological roles in the CNS and is associated with the protective killing function of macrophages and microglia. In contrast to the physiological roles of normal NO levels, excessive NO produced under pathological settings can act as a potent neurotoxin in a number of neurodegenerative models (Dawson and Dawson, 1998). Excess NO reacts with superoxide species to form peroxynitrite, which readily crosses cell membranes and contributes to nitrotyrosine formation on proteins such as α -synuclein and SOD1 (see section 44.2.2. Protein Nitration). In sporadic PD and some animal models, neuronal NOS (nNOS) and iNOS are both upregulated, while genetic ablation or pharmacological inhibition of excess NO production is neuroprotective in the MPTP model (Przedborski et al., 1996; Liberatore et al., 1999). In ALS patients, expression of nNOS and eNOS as determined by immunohistochemistry is significantly higher than that found in controls (Kashiwado et al., 2002), and iNOS expression among spinal cord infiltrates have been noted.

44.3.2.1. DNA Modifications

Modification of nucleic acids by free radicals and reactive species can induce chromosomal aberrations with high efficiency, suggesting that chromosomal damage exhibited in neurons of PD patients might be related to an abnormally high oxidative stress. Among the most promising biomarkers of oxidative damage to nucleic acids is nucleoside 8-hydroxyguanosine (8-OHG) for RNA or 8-hydroxy-2'-deoxyguanosine (8-OHdG) for DNA. 8-OHG is an oxidized base produced by free radical attack on DNA by C-8 hydroxylation of guanine and is one of the most frequent nucleic acid modifications observed under conditions of oxidative stress. In PD patients, levels of 8-OHG nucleic acid modifications are commonly increased in the caudate and SN compared to age-matched controls (Zhang et al., 1999). Immunohistochemical characterization of these modifications indicates that the highest levels of 8-OHG modifications are found in neurons of the SN and to a lesser extent in neurons of the nucleus raphe dorsalis and oculomotor nucleus, and occasionally in glial cells. Given that 8-OHG nucleic acid modifications are rarely detected in the nuclear area, mostly restricted to the cytoplasm, and that immunoreactivity is significantly diminished by RNase or

DNase and ablated with both enzymes (Zhang et al., 1999), suggests that targets of oxidative attack include both cytoplasmic RNA and mitochondrial DNA. Of particular interest are the findings that concentrations of 8-OHG in CSF of PD patients are higher than in age-matched controls; however, serum concentrations of 8-OHG appear highly variable (Abe et al., 2003).

In ALS, 8-OHdG modified DNA is detected in spinal cord tissues (Calingasan et al., 2005) and CSF (Ihara et al., 2005) from sporadic ALS (SALS) and FALS patients, while levels of nuclear 8-OHdG are increased in motor cortex of SALS patients, but not FALS patients (Shibata et al., 2000).

44.3.2.2. Lipid Peroxidation

4-Hydroxy-2-nonenal (HNE) is a reactive α,β unsaturated aldehyde that is one of the major products during the oxidation of membrane lipid polyunsaturated fatty acids, and forms stable adducts with nucleophilic groups on proteins such as thiols and amines. HNE modification of membrane proteins forms stable adducts that can be used as biomarkers of cellular damage due to oxidative stress. Immunochemical staining on surviving dopaminergic nigral neurons in the midbrains of PD patients show the presence of HNE-modified proteins on 58% of the neurons compared to only 9% of those in control subjects, weak or no staining on oculomotor neurons in the same midbrain sections from PD patients (Yoritaka et al., 1996), and their presence in LB from PD and diffuse LB disease patients, but not age-matched controls (Castellani et al., 2002). HNE species are typically more stable than oxygen species, thus they can easily spread from site of production to effect modifications at a distant site. HNE modifications of DNA, RNA, and proteins have various adverse biological effects such as interference with enzymatic reactions and induction of heat shock proteins, and are considered to be largely responsible for cytotoxic effects under conditions of oxidative stress (Toyokuni et al., 1994). The cytotoxic effects of HNE modifications may be in part due to inhibition of complexes I and II of the mitochondrial respiratory chain; induction of caspase-8, -9, and -3, cleavage of poly(ADP-ribose) polymerase (PARP) with subsequent DNA fragmentation; inhibition of NF- κ B mediated signaling pathways; or diminution of glutathione levels. Consistent with an abundance of data showing the dysregulation of proteasomal function in PD, direct binding of HNE to the proteasome also inhibits the processing of ubiquitinated proteins. Levels of HNE species that induce no acute change in cell viability *in vitro* initially cause a decrease in the proteasomal catalytic activity to the extent that it those levels induce accumulation of ubiquitinated and nitrated proteins, reductions in glutathione levels and mitochondrial activity, and increased levels of oxidative damage to DNA, RNA, proteins, and lipids (Hyun et al., 2003).

In SALS patients, HNE levels are significantly elevated in the sera, CSF, the ventral motor neurons and surrounding glia (Shibata et al., 2000; Simpson et al., 2004). Levels in serum

and CSF are directly correlated with the extent of the disease, but not with the rate of disease progression and are cytotoxic to a hybrid motor neuron cell line. One HNE-modified protein was shown to be the astrocytic transporter EAAT2, (Pedersen et al., 1998) suggesting a role for HNE-mediated impairment of glutamate transport, increased glutamate levels and excitotoxic-induced neurodegeneration in ALS.

44.3.2.3. *Glutathione*

Production of ROS and NO in neurons is buffered primarily by the glutathione (GSH) system. GSH content in the SNpc of PD patients is decreased by 40–50%, but not in other regions of the brain, nor in age-matched controls or patients with other diseases affecting dopaminergic neurons (Sian et al., 1994b). This diminution continues with progression and severity of disease, suggesting a correlation with concomitant increases in reactive species (Pearce et al., 1997). GSH depletion has been suggested as the first indicator of oxidative stress during PD progression, possibly occurring prior to other hallmarks of PD including the decreased activity of mitochondrial complex I (Andersen, 2004). Also, elevated GSSG/GSH ratios in PD patients (Sian et al., 1994b) argue strongly for a role of oxidative stress in this disease (Dringen, 2000). An increase in glutathione peroxidase immunoreactivity, exclusive to glial cells surrounding surviving dopaminergic neurons, has also been observed in PD brains (Damier et al., 1993). Interestingly, the SN and striatum have lower levels of GSH relative to other regions of the brain, which include, in increasing order: SN, striatum, hippocampus, cerebellum, and cortex (Kang et al., 1999). Although varying in different regions of the brain, all GSH levels diminish by about 30% in the elderly, suggesting a possible link with the age associated risk factor for PD. GSH depletion cannot be explained by increased oxidation of GSH to GSSG as levels of both are diminished in the nigra of PD patients (Chen et al., 1989; Sian et al., 1994b). Diminished GSH levels do not appear to be caused from failure of GSH synthesis as γ -glutamylcysteine synthetase is unaltered, as are glutathione peroxidase and glutathione transferase activities (Sian et al., 1994a). Other possible mechanisms for diminished levels include increased removal of GSH from cells by γ -glutamyltranspeptidase (Sian et al., 1994a) and the formation of adducts of glutamyl and cysteinyl peptides of GSH with dopamine. Nevertheless, depletion of GSH may render cells more sensitive to toxic effects of oxidative stress and potentiate the toxic effects of reactive microglia (Chen et al., 2001).

In contrast, direct evidence for perturbations of the glutathione system in ALS is limited. One report demonstrated in the CSF of SALS patients, increased oxidized NO products, higher GSH levels and lower GSSH levels, thus lower GSSH/GSH ratios (Tohgi et al., 1999); however GSH or GSSH levels in brain or spinal cord tissues remains to be determined. In addition, reports of increased GSH-binding sites in the spinal cord of ALS patients could reflect an upregulation of glutathione receptors (Bains and Shaw, 1997).

44.3.3. Modulation of Innate Immunity as Therapeutic Targets

44.3.3.1. *PPAR- γ*

Immune suppression through receptor modulation has been another approach attempted to alleviate or reverse PD progression. For example, agonists of peroxisome proliferator-activated receptor- γ (PPAR- γ), a nuclear receptor involved in carbohydrate and lipid metabolism, have been shown to inhibit inflammatory responses in a variety of cell lines, including monocyte/macrophages and microglial cells (Breidert et al., 2002). *In vivo* administration of PPAR- γ agonists modulates inflammatory responses in the brain. Pioglitazone, a PPAR- γ agonist used currently as an anti-diabetic agent, has been shown to have anti-inflammatory effects in animal models of autoimmune disease, attenuate glial activation, and inhibit dopaminergic cell loss in the SN of MPTP treated mice (Breidert et al., 2002). However, pioglitazone treatment had little effect on MPTP-induced changes in the striatum. This result seems to indicate that in the MPTP mouse model of PD, mechanisms regulating glial activation in the dopaminergic terminals compared with the dopaminergic cell bodies are PPAR- γ independent (Breidert et al., 2002).

44.3.3.2. *Minocycline and Modulators of Microglial Activation*

Minocycline, a semisynthetic second generation tetracycline, easily penetrates the blood-brain barrier and has been shown recently to effectively protect from neurodegeneration in several disease models including ALS, PD, cerebral ischemia, Huntington's disease, multiple sclerosis, and spinal cord injury (Domercq and Matute, 2004), all of which involve microglial activation as the principle effector of secondary neurotoxicity. Tetracyclines prevent cell death in models of neurodegeneration by both attenuation of the innate and adaptive immunity and blockage of apoptotic cascades (Domercq and Matute, 2004). Minocycline specifically inhibits microglial activation and proliferation, the induction of caspase-1 and -3, iNOS, and COX-2 (Chen et al., 2000; Domercq and Matute, 2004; Wang et al., 2004). Minocycline also attenuates adaptive immunity by reducing the expression and activity of matrix metalloproteinases, which alter blood-brain barrier permeability (Brundula et al., 2002; Popovich et al., 2003; Zhu et al., 2002; Domercq and Matute, 2004). Oral administration of minocycline was able to attenuate microglial activation, protect dopaminergic neurons in the SNpc, and restore motor function in the MPTP mouse model of PD (Peng et al., 2006). Administration of minocycline was also effective in ALS transgenic mice. Not only was the effect of treatment to delay onset of disease, it resulted in increased motor performance and extended survival by 2–3 weeks compared to non-treated ALS transgenic mice (Zhu et al., 2002; Kriz et al., 2002). Other modalities that have been used successfully to

attenuate microglia activation in models of neurodegeneration include non-steroidal anti-inflammatory agents (Dairam, 2006), COX-2 inhibitors such as rofecoxib (Hewett, 2006) and parecoxib (Reksidler, 2007), and dextromethorphan (Zhang, 2006) among others (Figure 44.1).

Free radical production by activated microglia accompanied by dysregulation of antioxidants (e.g., SOD, glutathione and catalase) diminish the protective potential by establishing a pro-oxidative stress environment. In turn, these antioxidants may be used therapeutically to modulate the microglial response. SOD levels have been shown to decline throughout the progression of PD. Direct treatment with SOD or inducers of SOD may be used to inactivate oxygen free radicals produced by activated microglia by converting superoxide to hydrogen peroxide which in turn is cleared by either catalase or glutathione peroxidase upon conversion to water, with GSH as the cosubstrate. Treatments that lead to increased expression of GSH or prevent its degradation may slow disease progression. These antioxidants can be used together to combat the microglial inflammatory response (Figure 44.1).

44.4. Adaptive Immunity

44.4.1. Cell-Mediated Immunity

While naïve T cells are typically precluded from CNS entry, neuroinflammation aggressively recruits activated components of the adaptive immune system to sites of active neurodegeneration by increasing expression of cellular adhesion molecules and inducing chemokine gradients. Moreover, glial cells secrete toxic factors that disrupt blood brain barrier function. Nonetheless, much evidence indicates a far more complex relationship between the CNS and immunological systems than previously thought. Further challenging this view of the “immune privileged” status of the CNS are animal model systems wherein immune deficiencies translate into exacerbated neuronal loss following traumatic injuries. Such injuries are corrected in animals that receive immune reconstitution prior to experimental injury. Rodents and humans that have sustained CNS injuries also have expanded T cell repertoires against myelin-associated antigens, yet do not appear to be at increased risk for the development of CNS autoimmunity. Any functional consequence of such T cell responses against CNS antigens following injury remains to be determined.

Little evidence exists for HLA association with PD. Early reports identified significant association of PD with expression of HLA-B17, -B18, -A2, and -A28, whereas later works failed to detect significant deviations of HLA haplotypes among PD patients compared to unaffected controls. Interestingly, a recent study analyzing HLA class I and II alleles among 45 German PD patients demonstrated a significant increase in the representation of the DQB1*06 allele suggesting an association between idiopathic PD and the immune system (Lampe et al., 2003).

The association of any one HLA type with ALS is controversial. Initial studies found no statistical association with ALS, however increased incidences of ALS patients that express HLA-A3, -Bw40, -Bw35, -B18, -Cw4, as well as decreased incidence of HLA-A9, -B8, -B7, and -DR4 were discovered. Additionally, milder disease progression is associated with HLA-A12 and -Bw40, whereas more aggressive disease is associated with HLA-Bw35.

In PD patients, increased numbers of CD8⁺ T cells are found in close proximity to activated microglia and degenerating neurons within the SN; however, those numbers are consistently low in frequency (McGeer et al., 1988a). In the MPTP mouse model, numbers of CD8⁺ and CD4⁺ T cells are significantly increased as late as day 21 post-intoxication with mean CD4/CD8 ratios of 0.33 ± 0.07 (range 0.19–0.64) (Kurkowska-Jastrzebska et al., 1999). Whether these infiltrating T cells are activated, antigen-specific, or migrating in response to microglial inflammation has yet to be determined, but the presence of major T cell subsets at levels exceeding those typically found in the CNS and in ratios differing from those found in the periphery suggests a role in PD more profound than that associated with surveillance. In that vein, numerous aberrations in peripheral lymphocyte subsets are detectable in PD patients. Compared to age-matched controls, numbers of total lymphocytes in both drug-naïve and -treated PD cohorts have been shown to be diminished by 17%, while CD19⁺ B cells were diminished by 35% and CD3⁺ T cells were diminished by 22% (Bas et al., 2001). Among CD3⁺ T cells, numbers of CD4⁺ T cells were diminished by 31%; whereas, numbers of CD8⁺ T cells were not significantly changed. The frequencies of cells within CD4⁺ T cell subsets are differentially diminished, with a greater loss of naïve helper T cells (CD45RA⁺) and either unchanged or increased effector/memory helper T cell subset (CD29⁺ or CD45RO⁺) (Bas et al., 2001).

That at least some T cell subsets from PD patients are activated is suggested by the increased mutual co-expression of CD4 and CD8 by CD45RO⁺ T cells, as well as upregulation of CD25 (α -chain of the IL-2 receptor), TNF- α receptors, and significant downregulation of IFN- γ receptors. However, evaluation of these parameters to assess whether activated T cell phenotypes are derived from any one T cell subset or many subsets have yet to be incorporated within one study. Interestingly, a significantly greater number of micronuclei and unrepaired single strand DNA breaks, which have been shown to result from exposure to higher levels of oxidative stress and inflammation (Cerutti, 1985), are detected in lymphocytes and activated T cells from PD patients compared to age-matched controls (Migliore et al., 2002; Petrozzi et al., 2002).

In ALS patients, lymphocytes, as well as myeloid cells are consistently found within or around affected tissues (Graves et al., 2004). Affected tissues with lymphocytic infiltrates include spinal cords, brain, muscles, and associated vessels (Graves et al., 2004). Most reports have identified the infiltrating lymphocytes as T cells, with a minor presence of B cells. Most indicate that both CD4⁺ and CD8⁺ T cells are present

within affected tissues, but one report indicated the presence of CD8⁺ T cells, with rare CD4⁺ cells in anterior and lateral corticospinal tracts and anterior horns (Troost et al., 1990), while another demonstrated the presence of primarily CD4⁺ T cells with rare CD8⁺ cells in muscle (Troost et al., 1992). Although not rigorously examined, a consensus suggests that these T cells are in an activated state by the presence of upregulated surface markers such as MHC I and II molecules (Lampson et al., 1990; Troost et al., 1992) and CD40L (CD40 ligand) (Graves et al., 2004). Of particular interest is the finding that PCR amplification of the third complementarity-determining region (CDR3) to examine the T cell receptor (TCR) repertoire of infiltrating T cells in cerebral spinal fluid (CSF), spinal cords and brains of ALS patients showed increased utilization of TCRBV2 (variable region 2 of the T cell receptor β -chain) transcripts which was independent of HLA haplotype (Panzara et al., 1999).

Early studies of ALS patient peripheral blood revealed a general loss of T cells as demonstrated by reduced numbers of E-rosetting T cells (a function mediated by CD2), and later confirmed by flow cytometric analysis showing significant losses of total CD2⁺ T cells with concomitant increase with increased numbers of surface Ig⁺ B cells (Provinciali et al., 1988), whereas others have failed to show significant differences in T or B cell frequency or function (Appel et al., 1986). Analyses of T cell subsets in ALS patients relative to normal controls show variable results, which include diminished or increased frequencies of CD4⁺ cells, diminished frequencies of CD8⁺ T cells, or no changes in either T cell subset. Of interest, frequencies of T cells that co-express IgM FcR (Fc μ R), MHC class II, CD38, or IL-13, all phenotypes functionally associated with immunoregulatory functions and/or activated states, are increased in ALS patients (Shi et al., 2006). Increased frequencies of T cells that express MHC class II and CD4⁺IL-13⁺ T cells are inversely correlated with clinical score, while the latter T cell phenotype directly correlates with the rate of disease progression (Shi et al., 2006). Of interest, in a minor subset of ALS patients with persistent motor conductance blockage, but not those without blockage, the frequencies of CD3⁺, CD4⁺, and CD8⁺ T cells, as well as CD16⁺ mononuclear cells are increased, suggesting a relationship between peripheral blood abnormalities and the pathogenic processes associated with conduction blockage in ALS patients (Tanaka et al., 1993).

44.4.2. Humoral Immunity

The possibility that humoral immunity may play a role in either the initiation or regulation of PD arose from observations of increased complement components in the SN of PD patients and experimental models wherein dopaminergic degeneration is triggered by adoptive transfer of immunoglobulin from PD patients. In both idiopathic and genetic cases of PD, pigmented dopaminergic neurons immunolabeled with IgG and associated with an increase in activated microglia expressing the high affinity IgG receptor Fc γ RI (Orr et al., 2005).

Perhaps the most studied of immune-associated aspects in ALS patients are those of humoral immunity. Global alterations of humoral immunity include increased serological complement (C'), γ -globulin and immunoglobulin levels, increased immune complexes, and the presence of immunoglobulin and C' component depositions within kidney, spinal cord and other nervous tissues of ALS patients. These humoral aberrations and depositions of humoral products provoked an increased impetus for an autoimmune approach to ALS etiology. Thus, many studies have assessed the possible antigenic reactivities of those antibodies. Those reactivities from ALS patients' sera and CSF comprise epitopes associated with nervous and non-nervous tissues as well. Nervous system specificities of antibodies in ALS encompass those directed against moieties from spinal cord, motor neurons, neuromuscular junctions, neurofilaments, myelin, and Ca²⁺ channels. The plethora of data showing antibody reactivities to gangliosides especially among IgM antibodies and their localization to motor neurons and spinal grey matter, dorsal and ventral spinal roots, dorsal root ganglion neurons, nodes of Ranvier, neuromuscular junctions and skeletal muscle is thought to reflect a possible pathogenic role in motor neuron diseases; however the mechanism by which those antibodies exact their toll has not been ascertained. Co-culture with neuronal tissues and passive transfer to rodent recipients of sera or immunoglobulin from patients and immunized animals has revealed functional consequences of these reactivities relative to ALS patients. Passive transfer yields increased presence of human IgG in spinal cord motor neurons and neuromuscular junctions with increased miniature end-plate potential (MEPP) frequency (Appel et al., 1991), increases in the rate of spontaneous neurotransmitter release, and axonal degeneration and denervation in most muscles (Uchitel et al., 1992). Within 12–24 hours of IgG transfer, increases are detected in the density of synaptic vesicles, CSF glutamate concentrations, and Ca²⁺ levels in axon terminals of neuromuscular junctions and synaptic boutons on spinal motoneurons (Engelhardt et al., 1995; Engelhardt et al., 1997; La Bella et al., 1997; Pullen et al., 2004). Antibodies are internalized with increased phosphorylation of neurofilament H (Engelhardt et al., 1995) while Golgi system and rough endoplasmic reticulum dilate with concomitant increased Ca²⁺ levels that are precipitously depleted after 24 hours (Engelhardt et al., 1997; Pullen et al., 2004). At 72 hours after transfer, CSF glutamate and aspartate levels increase, without appreciable change in glutamine and glutathione levels (La Bella et al., 1997). By 8 days post-transfer, areas of neuronal cell necrosis are evident (Pullen et al., 2004) and sensitivity to L-type Ca²⁺ channel blockers is retained for up to 4 weeks post transfer (Fratantoni et al., 2000). Thus, passive transfer of immunoglobulin from ALS patients appears to lead to long-lasting effects of motor neurons at the neuromuscular junction and may indicate that such effects may be an early stage event in immune-mediated pathogenesis of ALS.

44.5. Therapeutic Immunoregulation

44.5.1. Cell-Mediated Immunomodulation

Another potential therapeutic avenue for PD may involve T cell mediated immune responses (Figure 44.1). Activation of T cells directed against antigens expressed at the injured areas of the CNS has been shown to be neuroprotective under acute and chronic neurodegenerative conditions (Kipnis et al., 2002). However, immunization with such antigens might lead to development of an autoimmune disease. Immunization with Copolymer-1 (Cop-1, Copaxone, glatiramer acetate) or passive transfer of Cop-1 specific T cells has been shown to be beneficial for protecting neurons from secondary degeneration after injurious conditions (Kipnis et al., 2000). Cop-1 reactive T cells have partial cross-reactivity with myelin basic protein (MBP) and other self-antigens expressed in the brain (Arnon and Sela, 2003). Therefore, immunization with Cop-1 leads to increased accumulation of T lymphocytes in areas of injury within the brain and spinal cord and is neuroprotective without causing any adverse effects; however, the molecular mechanism of this response is not fully understood. T cells reactive to Cop-1 could be a source of brain-derived neurotrophic factor (BDNF) and other neurotrophic factors (Kipnis et al., 2000) or can induce production of neurotrophins by microglial or astroglial cells. Recently, the neuroprotective effect of immunization with Cop-1 was tested in the MPTP model of PD and demonstrated that adoptive transfer of Cop-1-specific T cells, but not ovalbumin-specific T cells, into MPTP-intoxicated mice attenuates reactive microglial neuroinflammation and inhibits dopaminergic neurodegeneration in both the SNpc and the striatum (Benner et al., 2004). Additionally, adoptive transfer of those T cells protects from the loss of nigral N-acetylaspartate (NAA) levels associated with MPTP-induced neurodegeneration as determined by quantitative proton magnetic resonance spectroscopic imaging (^1H -MRSI) (Boska et al., 2005). Suppression of microglial-associated inflammation was associated with T cell accumulation within the SNpc, induction of a T helper type 2 cell (Th2) response with production of anti-inflammatory cytokines (IL-4, IL-10), and increased expression of GDNF by astrocytes, but not by infiltrating T cells or microglia (Benner et al., 2004). Recent studies have shown that CD4^+ T cells, rather than CD8^+ T cells, possess greater neuroprotective capacity and that passive transfer of anti-Cop-1 antibodies provide no neuroprotection (Laurie et al., 2007). More recently, we demonstrated that adoptive transfer of anti-CD3 activated CD4^+ CD25^+ regulatory T cells (Tregs), but not activated effector T cells, are capable of ameliorating MPTP-induced neuroinflammation and dopaminergic neurodegeneration (Reynolds et al., 2007). Moreover, Tregs were shown to mediate neuroprotection through suppression of reactive microglia responses to inflammatory stimuli including nitrated α -synuclein, as well as enhancing astrocyte-derived GDNF. In a mouse model of ALS, immunization with Cop-1 has been shown to extend sur-

vival by 25% in the G93A mSOD1 transgenic mice (Angelov et al., 2003). These data suggest a putative mechanism for which regulatory T cells, induced by vaccination with cross-reactive epitopes or activated regulatory T cells, extravasate in response to neuroinflammation from neurodegenerative processes; secrete anti-inflammatory cytokines in response to cross-reactive self-epitopes (e.g., myelin basic protein) to attenuate reactive microglia; suppress the inflammatory response; and induce neurotrophic responses by T cells and/or other glia (Figure 44.3).

The recent development of novel immune-mediated therapeutic vaccine strategies for disease intervention and attenuating neuroinflammation are predicated on the ability of regulatory T cells, either induced or naturally occurring, to modulate both innate and adaptive immune responses and suppress inflammation both in autoimmune disease and in models of neurodegeneration. Treatment with VIP is emerging as a therapeutic tool to generate Tregs both *in vitro* and *in vivo*. VIP originates as a neuropeptide that can function as both a neurotransmitter and neuromodulator in many organ systems, including the central and peripheral nervous systems (Said, 1976). VIP-containing neurons are present in the CNS in areas that influence the immune system as well as in lymphoid organs, and are thought to be involved in the recruitment of immune cells, many of which express receptors for VIP (Kaltreider et al., 1997; Reubi et al., 1998; Reubi et al., 2000). VIP is also produced by lymphocytes, preferentially Th2 T cells, in response to different mitogenic or inflammatory stimuli (Gomariz et al., 1990; Gomariz et al., 1992; Leceta et al., 1996; Delgado et al., 2005). Th2-derived VIP also promotes Th2 responses *in vivo* (Delgado et al., 1999; Delgado et al., 2000; Goetzl et al., 2001; Vassiliou et al., 2001; Delgado et al., 2002; Voice et al., 2003). VIP treatment was recently shown to be efficacious in inducing Tregs in a variety of inflammatory disorders including arthritis, graft versus host disease, and more recently experimental allergic encephalitis (Delgado et al., 2005; Fernandez-Martin et al., 2006). VIP has also been used to expand regulatory T cells *ex vivo* and elicit conversion of CD4^+ CD25^- effector T cells to Tr1 regulatory T cells. Thus, VIP can be utilized to generate Tregs specific for self-antigens to promote antigen-specific tolerance and suppress development of autoimmune disorders in a variety of animal model systems (Figure 44.1) (Delgado et al., 2005; Fernandez-Martin et al., 2006; Gonzalez-Rey et al., 2006).

Selective activation of particular subsets of dendritic cells (DCs) with GM-CSF or 1,25-dihydroxyvitamin D3 (Figure 44.1) can not only activate lymphocytes, but also induce T cell tolerance to self-antigens or to specific antigens tandemly administered as immunization or tolerization regimens. DCs also can affect B cell function, antibody synthesis, and isotype switching. Recent studies have shown that DCs stimulated with GM-CSF or 1,25-dihydroxyvitamin D3 may exert their tolerogenic functions through arresting type 1 helper T cells (Th1), skewing the Th1/Th2 balance, and generating regulatory T cells (Gregori et al., 2002; Vasu et al., 2003; Gangi et al., 2005).

FIGURE 44.3. T cell-mediated neuroprotection in a PD model. In MPTP-intoxicated mice, regulatory T cells infiltrate the inflamed nigrostriatal pathway where they encounter cross-reactive CNS antigens (such as myelin basic protein or reactive species-modified proteins) presented in the context of MHC by resident microglial cells. In response, activated T cells secrete anti-inflammatory cytokines such as IL-4, IL-10, and TGF- β that suppress toxic microglial activities. Neurotrophin expression may occur directly from T cells or T cell-derived IL-4, and IL-10 may induce neurotrophin production in neighboring glia. These activities lead to neuroprotection indirectly by suppression of microglial responses and directly through the local delivery of neurotrophins.

44.5.2. Modulation of Humoral Immunity

Using another vaccine strategy to elicit humoral immune responses directed at cephalic epitopes, immunization of human α -synuclein transgenic mice with mutant human α -synuclein produced high affinity anti- α -synuclein antibodies with concomitant diminution of human α -synuclein inclusions in neurons and synapses, and diminished neurodegeneration (Masliah et al., 2005). Moreover, anti- α -synuclein antibodies recognized abnormal human α -synuclein and supported degradation of α -synuclein aggregates. Similarly, immunization of G37R SOD1 transgenic mice with recombinant mutant SOD1 reduced the amount of mutant SOD1 in spinal cords of immunized mice, increased numbers of surviving motor neurons, and extended their life span by greater than

4 weeks, which significantly correlated with increasing anti-SOD1 antibody titers (Urushitani et al., 2007). In contrast, this strategy failed to protect G93A SOD1 mice, which exhibit a more severe and aggressive phenotype than G37R SOD1 mice, however ventricular infusion of purified anti-human SOD1 antibody alleviated clinical signs and significantly extended life span by 4%. These data provide support for immunotherapeutic strategies that target extracellular burdens of aggregated or misfolded toxic proteins such as α -synuclein and SOD1 in neurodegenerative disorders (Figure 44.1).

44.5.3. Other Vaccine Strategies

One quasi-immunotherapeutic strategy targets intracellular accumulation of toxic proteins in neuron by using single

chain antibodies (scFv) or intrabodies (Chen et al., 1994). This strategy is accomplished by preventing misfolding to the toxic form, interfering with misfolded protein interactions, or enhancing degradation of the toxic form. Clearly keys to this strategy are the production of scFv with affinities that retain epitope specificities *in vivo* and efficacious delivery to vulnerable or affected neurons. For delivery, genes encoding the scFv must be transfected into target cells and successfully expressed as a functional intrabody. To date several scFv to α -synuclein have been prepared (Emadi et al., 2004; Miller et al., 2005; Barkhordarian et al., 2006; Maguire-Zeiss et al., 2006; Emadi et al., 2007). Several specific scFv have been shown to recognize different conformations of α -synuclein and upon co-incubation with monomeric α -synuclein *in vitro*, to decrease the rate of α -synuclein aggregation, inhibit formation of oligomers and protofibrils, and inhibit toxicity. In transfected cells, scFv have been shown to be stably expressed with minimal toxicity for greater than 3 months, bind intracellular α -synuclein, increase the amount of detergent soluble α -synuclein species while decreasing the amount of insoluble species, and counter reduced cell adhesion which characterizes cells that overexpress α -synuclein (Messer and McLear, 2006). Thus, scFv to α -synuclein have the potential to provide a therapeutic modality to control intracellular accumulation of toxic protofibrillar forms of α -synuclein and possibly disease progression (Figure 44.1).

Therapeutic vaccine approaches using neuronal antigens represent a potential efficacious interdictory modality for slowing or halting the progression of neuroinflammation and secondary neurodegeneration and removing neurotoxic aggregates (Figure 44.1). These approaches should be considered in strategies with other anti-inflammatory or anti-oxidant therapies for a combinatorial modality to protect against neuroinflammation and consequent neurodegeneration in PD and ALS. For the latter, clinical trials have recently been completed demonstrating the safety and immunological responsiveness to glatiramer acetate (GA) vaccine therapy in ALS patients (Gordon et al., 2006). Work performed in our own laboratories assessed cell-mediated, cytokine and humoral responses in ALS patients who received GA during the six-month phase II trial. Treated patients showed enhanced lymphocyte proliferation to GA. Plasma samples were evaluated by GA-specific ELISA assays for immunoglobulin (Ig) classes (Ig M, A, and G) and IgG subclasses (IgG1, IgG2, IgG3, and IgG4), and by cytokine bead arrays (CBA) for Th1 and Th2 cytokine levels (Mosley et al., 2007). Fourteen of 21 GA-immunized patients produced anti-GA Ig responses. All anti-GA IgG subclass concentrations were increased by greater than 4.2-fold in plasma from treated patients, and anti-GA IgG1 comprised the majority of the humoral response. Additionally, changes in plasma Th1 and Th2 cytokine levels were shown to be associated with time of GA treatment. These data show significant humoral responses and cytokine trends following GA immunization in ALS patients.

44.6. Neuroprotective Strategies

44.6.1. Growth Factors

The role of neurotrophins in reducing neurodegeneration and promotion of neuroregenerative processes presents an exciting possibility for therapeutic benefit to PD (Figure 44.1). A study of lentiviral delivery of glial cell line-derived neurotrophic factor (GDNF) showed trophic effects on degenerating nigrostriatal neurons in a primate model of PD (Kordower et al., 2000). Results indicated augmented dopaminergic function in aged monkeys and reversal of functional deficits with complete prevention of nigrostriatal degeneration in MPTP-treated monkeys. These data indicate that GDNF delivery using a lentiviral vector system can prevent nigrostriatal degeneration and potentially induce regeneration in primate models of PD, showing the potential for a viable therapeutic strategy for PD patients. However, recent clinical trials of intraputamenally infused GDNF in PD patients are controversial with one 2-year phase I trial showing improved activity scores and no untoward effects in a limited cohort (Patel et al., 2005), while phase II trials were halted after six months due to lack of efficacy and adverse effects in patients and nonhuman primates.

44.6.2. Neuroprotectants

Many diverse mechanisms, factors, and pathways are involved in neurodegenerative disorders, thus several different therapeutic methods have been developed to target a specific factor or a whole intricate pathway with the intent of ameliorating, preventing, or reversing neuronal cell damage. Inflammation and oxidative stress form a commonality between many neurodegenerative diseases; therefore most therapeutic modalities currently under investigation target MP activation to decrease the magnitude of the inflammatory responses. The targets of these therapies include, but are not restricted to, enhancement of neurotrophic factors such as glia cell-line derived neurotrophic factor (GDNF), up-regulation of anti-inflammatory cytokines (IL-4, IL-10, and TGF- β 1), inhibition of enzymatic activities that encourage neurotoxicity (GSK-3 β , γ -secretase), Ca²⁺ and glutamate excitotoxicity blockers that inhibit NMDA receptor function, suppression of neuronal cytotoxicity (memantine, lithium, sodium valproate), and attenuation of inflammation by anti-inflammatory drugs (NSAID, minocycline). Anti-inflammatory and/or anti-oxidative therapies could be used in conjunction to form combinatorial therapies targeting multiple sites of oxidative stress that contribute to inflammatory responses and progressive degenerating disease (Figure 44.1).

44.7. Genetics and Immunity

Recent evidence has shown that genetics may contribute to the onset of neurodegenerative disorders (Li et al., 2002). Linkages to the age at onset (AAO) for PD have been identified

on chromosomes 1 and 10. The latter is significantly associated with glutathione s-transferase omega-1 (GSTO1) (Li et al., 2003); a provocative finding since GSTO1 is thought to be involved in the post-translation modification of IL-1, a major component in the regulation of inflammatory responses (Laliberte et al., 2003). One factor associated with the chromosome 1p peak is the embryonic lethal abnormal vision 4 (ELAVL4) gene (Noureddine et al., 2005), a human homologue of the *Drosophila* ELAV (Good, 1995) and essential for temporal and spatial gene expression during CNS development. Additionally, ELAVL gene products are known to bind to AU-rich response elements (ARE) in the 3'-untranslated region (3'UTR) of inflammation-associated factors (Good, 1995). Interestingly, PD patients homozygotic for allele 1 at position -511 of the IL-1 β gene have an earlier onset of the disease than those homozygotic for allele 2, which produces higher amounts of IL-1. Thus, higher production of IL-1 β may provide some neuroprotective effect for dopaminergic neurons (Nishimura et al., 2000; Mizuta et al., 2001). Gene expression analyses of post-mortem specimens have shown differentially expressed genes associated with the immune response in ALS, most notably IL-1 receptor accessory protein (IL-1rap), MHC class II, thromboxane synthase, Fc ϵ R γ -chain and the cytokine regulated upon activation, normal T-cell expressed and secreted (RANTES) (Malaspina and de Belleruche, 2004; Wang et al., 2006). Of interest, as most of these analyses are performed with tissues from end-stage patients, only approximately 10% of the differentially expressed genes expressed in ALS patients are associated with inflammation/immune function, whereas the majority of genes pertain to stress-activated pathways (Malaspina and de Belleruche, 2004). This is in contrast to mice that express the G93A mutation of the human *SOD1* wherein the majority of early changes are associated with inflammation/immune function genes.

Summary

Although patterns of neuronal degeneration are unique in PD and ALS, both disorders share common pathways and processes that support and possibly initiate neurodegeneration. Most of these processes are associated with induction, propagation, or consequences of neuroinflammation. Increased numbers of microglia that express a reactive phenotype and proximate dying neurons reflect the neuroinflammatory cellular response. Neuroinflammation amplifies oxidative stresses via reactive oxygen, nitrogen, and carbon species that then react with biomolecules and increase molecular modifications of lipids, proteins, and nucleic acids. These reactive modifications eventually become deleterious to biochemical and cellular processes resulting in dysregulation of cellular functions and further neuronal death. Whether neuroinflammatory responses are causal or consequential remains to be determined. Nevertheless, the importance of inflammatory responses to neurodegeneration is underscored in animal

models whereby attenuation of neuroinflammation by genetic manipulation or pharmacological agents mitigates neurodegeneration and increases neuronal survival. As such, immunological strategies that target neuroinflammatory processes represent promising candidates for therapeutic intervention in neurodegenerative disorders. These strategies embrace the capacity of regulatory T cells to protect neurons either directly via neurotrophic factors, or indirectly by modulation of microglial function to attenuate neuroinflammatory responses and by induction of astrocyte-derived neurotrophic factors.

Review Questions/Problems

- Summarize the evidence for innate immune-mediated mechanisms associated with PD.**
- Summarize the evidence that suggest a role for adaptive mediated immunity in ALS.**
- The cellular target for immunotherapy that would be most beneficial to inhibit secondary neurodegeneration is the**
 - astrocyte
 - neuron
 - microglia
 - oligodendrocyte
- The primary producer of reactive oxygen species by microglia is**
 - dopamine synthesis
 - NADPH oxidase
 - myeloperoxidase
 - superoxide dismutase
- In PD, postmortem samples show increased**
 - reactive microglia.
 - loss of striatal dopaminergic termini
 - loss of dopaminergic neuronal bodies within the substantia nigra pars compacta
 - reactive oxygen species modified proteins
 - all of the above
- CD45RO⁺ T cells that mutually express CD4 and CD8 more likely indicate those cells are**
 - dead
 - recent thymic emigrants.
 - anergic
 - activated

7. **An example of free radical modification of RNA is**
 - a. 8-hydroxyguanosine (8-OHG)
 - b. 4-hydroxy-2-nonenal (HNE)
 - c. 3-nitrotyrosine (NT)
 - d. 8-hydroxy-2'-deoxyguanosine (8-OHdG)
8. **Free radical modification of DNA is best exemplified by**
 - a. 8-hydroxyguanosine (8-OHG)
 - b. 4-hydroxy-2-nonenal (HNE)
 - c. 3-nitrotyrosine (NT)
 - d. 8-hydroxy-2'-deoxyguanosine (8-OHdG)
9. **One molecular marker of nitric oxide modification of proteins is**
 - a. 8-hydroxyguanosine (8-OHG)
 - b. 4-hydroxy-2-nonenal (HNE)
 - c. 3-nitrotyrosine (NT)
 - d. 8-hydroxy-2'-deoxyguanosine (8-OHdG)
10. **A protein marker resulting from modifications due to lipid peroxidation is**
 - a. 8-hydroxyguanosine (8-OHG)
 - b. 4-hydroxy-2-nonenal (HNE)
 - c. 3-nitrotyrosine (NT)
 - d. 8-hydroxy-2'-deoxyguanosine (8-OHdG)
11. **Immunotherapeutic strategies using scFv directed against α -synuclein targets are designed to**
 - a. prevent misfolding to the toxic form of the protein
 - b. interfere with misfolded protein interactions
 - c. enhance degradation of the toxic protein form
 - d. all of the above
12. **Passive transfer of sera or immunoglobulin from ALS patients to rodent recipients results in increases in the following sequelae with the exception of**
 - a. denervation of striatum
 - b. denervation of muscles
 - c. human immunoglobulins in spinal cord motor neurons
 - d. human immunoglobulins in neuromuscular junctions
 - e. miniature end-plate potential (MEPP)
13. **A ligand utilized for in vivo imaging of reactive microglia via upregulated peripheral benzodiazepine receptors is**
 - a. CFT
 - b. DA

45.1. Introduction

Neurodegenerative diseases are generally considered to be non-inflammatory, unlike autoimmune diseases such as multiple sclerosis, which are neurodegenerative diseases that are inflammatory in nature (Trapp et al., 1999a, b; Hohlfeld and Wiendl, 2001; Groom et al., 2003). Nevertheless, most neurodegenerative diseases are accompanied by a local inflammatory response, widely assumed to be unfavorable for CNS recovery (Kurosinski and Gotz, 2002; Jellinger, 2003; Popovich and Jones, 2003). Moreover, the progressive degeneration seen in such diseases is often mediated by compounds and processes that are secondary to the primary risk, e.g., misfolding and aggregation of self-proteins (Shastry, 2003). These primary and secondary risk factors represent a continuous threat to any viable neurons embedded in a chronically diseased tissue; they induce abnormalities in cells in their vicinity, thereby contributing to the chaos rather than helping to resolve it.

Another feature common to most of the chronic neurodegenerative conditions is age dependence. The incidence of Alzheimer's and Parkinson's disease, glaucoma, and many others increases significantly with age (Ossowska, 1993; Mattson, 2003). As will be discussed below the age factor might not be related only to the aging of the brain but also to age-related changes in the immune system. Often the removal of the primary risk factor does not stop disease progression, and the neurodegeneration continues (Weinreb and Levin, 1999; Schwartz and Cohen, 2000). In Parkinson's disease, for example, despite dopamine (L-dopa) treatment as a replacement therapy the dopaminergic neurons continue to die (Hirsch, 1999; Montastruc et al., 1999). In glaucoma, reduction of intraocular pressure often does not stop disease progression (Schwartz et al., 1996). This progressive degeneration, which continues despite removal of the presumed

primary risk factor(s), has been linked to what has been recognized as secondary degeneration. Emerging risk factors have been attributed to this phenomenon, including inflammation-associated factors. This has been studied intensively in recent years with a major focus on the balance between the benefit and the risk of uncontrolled immune activity, which exceeds the ability of the CNS to tolerate it.

45.1.1. Inflammation—A Local Response in Acute CNS Insults: Is It Always Bad?

The function of inflammation after any acute or chronic insult to the CNS has long been a matter of debate. Concepts such as the immune-privileged status of the CNS, as well as observations such as the presence of immune cells in the diseased CNS, gave rise to the prevailing belief that immune activity in the CNS is detrimental (Lotan et al., 1994). Many researchers consider inflammation to be an important mediator of secondary damage (Dusart and Schwab, 1994; Carlson et al., 1998; Fitch et al., 1999; Popovich et al., 1999; Mautes et al., 2000). Fitch et al. (1999) demonstrated that inflammatory processes alone can initiate a cascade of secondary tissue damage, progressive cavitation, and glial scarring in the CNS, and they suggested that specific molecules which promote inflammation might play a role in initiating secondary neuropathology (Fitch et al., 1999). This is apparently in line with the finding that removal of macrophages after SCI might improve the functional outcome (Popovich et al., 1999), and with the reported observations that the anti-inflammatory compound methylprednisolone promotes recovery in spinally injured rats (Constantini and Young, 1994). Other studies, however, indicate that local immune activity may have a beneficial effect on the traumatized spinal cord through clearance of cell debris and secretion of neurotrophic factors and cytokines. Macrophages and microglia promote axonal regeneration by clearing the site of injury (David et al., 1990; Perry et al., 1992; Madsen et al., 1998; Rapalino et al., 1998; Fitch et al., 1999; Fischer et al., 2004), and T cells mediate processes of maintenance

and repair and promote functional recovery from CNS trauma (Moalem et al., 1999b; Hauben et al., 2000a, b; Schwartz et al., 2001; Ling et al., 2006). Guth and his colleagues suggested a therapeutic combination of anti-inflammatory drugs such as allapenol (to inhibit injury-induced xanthine oxidase), indomethacin (to inhibit constitutive and inducible cyclooxygenase), and bacterial lipopolysaccharide (LPS) to stimulate macrophage activity. The short-term effect of the suggested therapy, however, while including both anti- and pro-inflammatory treatment, appears to be different from its long-run effect. Along the same lines, it was suggested that animals with limited ability to undergo Wallerian degeneration might suffer from limited wound healing and regeneration (Zhang and Guth, 1997). These and other studies led researchers to acknowledge that some aspects of inflammation have negative effects on recovery, whereas others are beneficial and even essential. (Bethea et al., 1999; Mason et al., 2001) As more and more pieces are added to the puzzle of post-traumatic CNS inflammation it becomes increasingly evident that to describe the effect of inflammation on the injured nerve as “good” or “bad” is an oversimplification, as it reflects the common view of inflammation as a single (and deleterious) process rather than as a series of local immune response that is primarily being recruited to cope with threat. Its ultimate benefit, lack of benefit, or even destruction is a reflection of regulation and timing and the ability of the tissue to cope with the harmful effects of the factors produced by the immune response. Conflicting interpretations of inflammation might thus reflect, the experimental injury model employed, the severity of the injury, time elapsed following injury, the markers used to identify locally activated immune cells, the species, and the strain. In addition, the choice immune-based manipulation used to demonstrate adverse effect is also critically affecting the outcome. Immune response being the physiological mechanism by which the body copes with damage, is essential for recovery, but is more constructive when suitably regulated.

45.1.2. Role of Innate Immunity in CNS Repair

Healing of tissue in response to injury involves the synchronized operation of numerous factors and processes, some of them operating in concert and others in sequence. It is essential that the set of processes occurring in the injured axons be synchronized with the set occurring in the cells surrounding the injured axons, such that the axonal environment acquires growth-supportive properties and the axons acquire growth activity. It seems plausible that the two sets of processes operate, but that the proper synchronization is lacking. Acquisition of growth supportive properties by the cellular milieu of the injured axons basically means achievement of a balanced environment for regrowth and cell renewal (Butovsky et al., 2001, 2005a, b, 2006; Ziv et al., 2006b). This synchrony might be achieved by an appropriate postinjury immune response that is compatible with the CNS ability to tolerate.

45.1.3. Lessons from Peripheral Nervous System—Wallerian Degeneration: Is It Needed for Repair?

Central nervous system (CNS) response to injury has long been viewed as though the CNS is a unique tissue whose behavior after injury is governed by different rules than those underlying the response of other types of injured tissues, including the peripheral nervous system (PNS). Accordingly, although failure of the CNS to regenerate has been intensively studied over the years, the usual approach has been to regard the CNS as atypical and therefore to study it as an entity distinct from any other tissue. On the assumption that CNS healing does not necessarily differ in principle from the healing of any other tissue, attempts to uncover the reasons for regeneration failure have begun to focus on comparisons, both phylogenetic and intraspecies, between regenerative and nonregenerative nervous systems. The loss of function following CNS injury has been attributed not only to the failure of regeneration but also to the secondary damage which is a mechanism whereby the spread of damage from directly injured neurons to neurons that escaped the primary lesion (Robertson et al., 2000; Schwartz and Yoles, 2000; Taoka et al., 2000; Schwartz, 2001a; Vajda, 2002; Wu, 2005). In the past two decades it has become clear that failure of CNS regeneration might be partly due to the inability of the cellular elements surrounding the injured axons to create a balanced environment capable of permitting and supporting regrowth (Caroni et al., 1988; Schwab and Bartholdi, 1996; Rapalino et al., 1998; Schwab, 2002). It was shown initially that transected CNS axons, which fail to regenerate in their own degenerative environment, were shown to be capable of growing into transplanted peripheral nerve bridges (Aguayo et al., 1984; So and Aguayo, 1985; Aguayo et al., 1987; Vidal-Sanz et al., 1987). Among the elements that were shown to be hostile to regrowth in adult CNS nerves, and are absent during development, are myelin-associated inhibitors (Tang et al., 2001; Domeniconi et al., 2002; Kim et al., 2004; Schwab et al., 2005). These inhibitors, over the years, have been fully characterized and are known as the NoGo family (Tatagiba et al., 1997; Merkler et al., 2003). NoGo has three major spliced isoforms (termed Nogo-A, -B and -C) that share similar domain structures. Proteins are highly expressed in oligodendrocytes, the longest of these, Nogo-A, has a large N-terminus followed by two putative membrane-spanning domains and a short C-terminal segment. The 66-amino acid segment (known as the Nogo-66 domain) between the two transmembrane domains is extracellular. A neuronal Nogo-66 receptor (NgR) that interacts in trans with the oligodendrocyte Nogo-66 domain has also been identified. Exogenous NgR expression in neurons that are otherwise not susceptible to Nogo-mediated growth inhibition confers inhibitory susceptibility, indicating that NgR could functionally transduce at least part of the inhibitory signal presented by Nogo. It was suggested that for regeneration to occur, these inhibitors must be either masked or eliminated. In the nervous systems of different species, the levels of such

inhibitors and/or the extent of their postinjury removal might correlate with regenerative capacity. For example, in mammalian CNS there is a high level of such inhibitors, whereas in lower vertebrates their level is lower and their removal seems to be more efficient (Lang et al., 1995; Hirsch and Bahr, 1999). Subsequent studies have identified additional myelin-associated proteins as inhibitors of regrowth, such as MAG (Tang et al., 2001; Domeniconi et al., 2002). In addition, it was suggested that the rate of myelin clearance from the CNS is significantly lower than from the PNS (Hofteig et al., 1981; Pellegrino et al., 1986; Stoll et al., 1989). Another set of studies have suggested that astrocytes, thought to be involved in scar formation, are needed for growth support, and their failure to support axonal growth after injury to the mammalian CNS might be related to their cellular properties and the nature of their extracellular milieu, such as production of chondroitin sulphate proteoglycan (Jones et al., 2002; Moon et al., 2002; Jones et al., 2003; Sandvig et al., 2004; Hofteig et al., 1981; Pellegrino et al., 1986; Stoll et al., 1989). Yet, recent studies from our laboratory have suggested that although the overall production of the CSPG might be inhibitory of regrowth, complete inhibition of its production worsened the overall recovery, its early production is needed but should be limited (Rolls et al. unpublished observation). Thus, it appeared that timing and intensity of the glial scar and the local immune response are critically determining the recovery, as is discussed below. These and other related findings suggest that the postinjury behavior of cells surrounding the injured axons might determine the regenerative capacity of the axons. (Dolenc, 1984; Ogawa et al., 1985; Dolenc, 1986; Angaut-Petit and Faille, 1987; Kalichman and Myers, 1987; Gu and Ma, 1991; Berkenbosch, 1992; Sivron et al., 1994; Bregman et al., 1995; Tidball, 1995; diZerega, 1997; Hirsch and Bahr, 1999; Best and Hunter, 2000; Fry, 2001; Kalla et al., 2001; Lakatos and Franklin, 2002; Cui et al., 2004; Fenrich and Gordon, 2004; Ferraro et al., 2004).

45.1.4. Macrophages/Microglia in CNS Repair

Wound healing is a complex, multistep process involving reciprocal interactions between immune cells from the circulation and resident cells of the tissue, with the participation of extracellular matrix proteins and an array of bioactive molecules with multiple actions. In most parts of the body, tissue injury triggers immediate infiltration of circulating immune cells into the damaged area. Twenty four hours after injury, infiltrating monocytes represent the majority of leukocytes at the site of injury. Migration and adhesion of monocytes are controlled by secreted factors, whose autocrine or paracrine activity promotes recruitment of those immune cells (Lazarov-Spiegler et al., 1999; Kalla et al., 2001). On reaching the tissue, the monocytes are locally activated and became 'alternatively' activated macrophages. The macrophages play a central role in wound healing by clearing debris from the injury site (Stoll et al., 1989; Schwab et al., 2001). Macrophages secrete cytokines, growth factors and enzymes into the

wound site, and participate in a profusion of autocrine and paracrine reactions with invading immune cells and resident tissue cells. When macrophages are eliminated by local injection of anti-leukocyte serum, or when monocyte production is prevented by injection of glucocorticoids, wound healing proceeds very slowly (Shirafuji et al., 2001, 2003).

In regenerating neural tissues, macrophages appear to be involved in both degeneration and regeneration. In the PNS, there is immediate Wallerian (i.e. anterograde) degeneration of the distal stump, involving the breakdown of axons and the fragmentation of Schwann cell cytoplasm. The invading monocytes play a major role in this process by clearing myelin debris and degenerating fibers, and by facilitating Schwann cell proliferation. In addition, they provide substances that participate in the healing process; for example, macrophage-derived apolipoproteins are expressed at the injury site and probably participate in membrane rebuilding. Nerve growth factor (NGF) synthesis seems to be regulated by the stimulated macrophages. Interleukin 1 and tumor necrosis factor α , secreted by macrophages, probably induce NGF transcription in Schwann cells (Stoll et al., 1989; Frisen et al., 1994; Schwab et al., 2000; Rotshenker, 2003; Stoll et al., 2004). Comparative *in vivo* and *in vitro* studies of the mammalian CNS and PNS have pointed to the part played by macrophages in the axonal response to injury, as well as to the link between macrophage activity and the success or failure of regeneration (Griffin et al., 1992; Giulian et al., 1995; Leskovar et al., 2000). In the CNS, in contrast to the PNS, macrophage infiltration following axonal injury is not only delayed but also restricted to the lesion site, rather than being dispersed along the part of the nerve through which the newly growing axons should elongate (Lazarov-Spiegler et al., 1998; Stichel et al., 1999; Wang and Feuerstein, 2000; Dihne et al., 2001; Schwartz, 2001a; Sekiya et al., 2001; Franzen et al., 2004). Furthermore, unlike in regenerative tissues, where invading blood-borne monocytes are the prominent inflammatory cells, in the CNS the resident microglia are considered to be the major mononuclear phagocytic participants at the site of injury. Following injury, activated microglia and infiltrating blood-borne macrophages are immunohistochemically indistinguishable. As the quiescent resident microglia in the intact CNS are thought to be in a down regulated form, it is possible that, following injury, the extent and the nature of their activation, in terms of acquiring healing-supportive activities, is limited compared with that of other tissue-resident macrophages. *In vitro* studies have shown, for example, that cytokines and growth factors associated with inflammation and wound healing have a significant effect on scar formation and/or dissolution. These factors appear to affect protease production, production of cross-linking enzymes (such as transglutaminase) and production of extracellular matrix proteins, all known significantly to affect the ability of astrocytes to support growth. Other studies have suggested that macrophage-derived factors have a cytotoxic effect on oligodendrocytes (Griot et al., 1989; Griot-Wenk et al., 1991; Zajicek et al., 1992). The above observations, together with other studies point to a link

between failure of CNS regeneration and the limitations in rate, activity and distribution of the immune cells in response to CNS injury.

45.1.4.1. *The Rationale for Macrophage Therapy and Its Preclinical Characteristics*

Experimental results over the last decade suggest that macrophages and brain microglia are multitasked cells that are capable of expressing different functional programs in response to distinct micro-environmental signals. Microbial products and cytokines profoundly affect the differentiation of monocytes towards two phenotypic extremes. Microbial products are associated with the “classical” activation of monocytes/microglia. The “classically” activated macrophages are potent effector cells that kill microorganisms and tumor cells. This “killer instinct” have been long viewed as the only the main function of microglia. In contrast, “alternatively” activated macrophages tune inflammatory response and adaptive immunity, scavenge debris, and promote angiogenesis, tissue remodeling and repair (Summers et al., 1995; Klusman and Schwab, 1997; Mantovani et al., 2002; Bomstein et al., 2003; Gordon et al., 2003; Hauben et al., 2003; Mosser, 2003). Similarly, microglia activated by adaptive immunity are microglia that can present antigens, produce growth factors, buffer glutamate and support cell renewal (Shaked et al., 2004; Butovsky et al., 2005a, b; Shaked et al., 2005; Butovsky et al., 2006).

Initial experiments in animals with complete spinal cord transection demonstrated that local application of macrophages that have been co-incubated with sciatic nerve promoted motor recovery (Lazarov-Spiegler et al., 1996; Rapalino et al., 1998). Subsequently, the experiments were repeated in a model of severe spinal cord contusion. In those experiments blood-borne monocytes were activated by co-incubation with autogenous skin (Bomstein et al., 2003). The results revealed that this was equally effective for recovery from spinal cord injury. In these and subsequent experiments, the macrophages were characterized phenotypically, and parameters such as site of injection, dosing and therapeutic window were studied. Those macrophages were found to have a dendritic-like phenotype (Bomstein et al., 2003) and expressed features that are reminiscent of ‘alternative activation’; production

of low levels of proinflammatory cytokines, and production of growth factors and metalloproteases. In subsequent studies aiming at finding the optimal time for intervention with local implantation of macrophages it became clear that as in any other tissue, repair and restoration are not only dependent on location and context, but also timing. Table 45.1 describes time windows representing a different physiological stages following SCI.

Taken together, the results summarized above as well as additional studies, it is suggestive that timely local innate immune cells with “alternative activity,” reminiscence of dendritic-like, are required for CNS ability to cope with injurious conditions, and that they are needed at the sub-acute phase following injuries.

45.2. Adaptive Immunity Is Needed to Control Local Innate Response in the CNS

45.2.1. Is Self and Non-Self Discrimination Needed?

“Survival of the fittest” summarizes the essence of Darwinian evolutionary theory. In line with this theory and the pioneering theory of Metchnikoff in the 1890s (Dubos, 1955; Vaughan, 1965), followed by the “clonal expansion” theory of Burnet in the 1950s (Miller, 1994; Silverstein and Rose, 1997; Martini and Burgio, 1999), it was believed that discrimination of self from non-self, thymic education of T cells, and deletion of auto-immune T cells in the thymus are the central features of immunology. Self-tolerance, defined as a state of non-responsiveness to self, was therefore viewed as the optimal condition, and was assumed to enable the fittest to survive (Viret et al., 1999). Studies carried out in rodent models of central nervous system (CNS) insults have suggested that autoimmunity is the body’s defense mechanism against any threat to CNS tissue (Schwartz and Cohen, 2000; Schwartz et al., 1999) and that only when the autoimmune response is poorly controlled will an autoimmune disease result. According to these observations and others, it emerged that defining tolerance to self in terms of non-responsiveness is incompatible with the theory of the survival of the fittest. A more appropriate definition of tolerance to self would

TABLE 45.1. Physiological stages following SCI.

Days post spinal cord injury	Description	Reference
3–4 days	A period reflecting the decline of primary infiltration of neutrophils participating in inflammation, and high incidence of apoptotic cells.	(Popovich et al., 1997; Leskovic et al., 2000)
7–10 days	A period of maximum accumulation of activated microglia/macrophages, T cells, and progenitor glial cells.	(Leskovic et al., 2000; McTigue et al., 2001)
14 days	The numbers of ED1 positive cells and T cells are still very high. At the same time different cytokines and chemokines in the injured tissue decrease or disappear.	(Lee et al., 2000; Leskovic et al., 2000; McTigue et al., 2001)
21 days	Many of the injury-induced biochemical and cellular activities in the spinal cord have peaked and begun to return to normal levels.	(Leskovic et al., 2000; McTigue et al., 2001)

be the ability to tolerate an anti-self response without developing an autoimmune disease (Schwartz and Kipnis, 2002). Just as the immune system fights off external pathogens, the autoimmune system fights off threats originating within the body itself (such as cancer, neurodegenerative conditions, tissue injuries), and also serves as a complementary defense mechanism against damage caused by external pathogens. Naturally occurring regulatory T cells ($CD4^+CD25^+$) serve as a physiological safety valve that can be modulated to maintain the fine balance between need and risk (Kipnis et al., 2002; Schwartz and Kipnis, 2002; Kipnis et al., 2004a).

In the early 1990s it became evident that there is little difference, between the T-cell repertoires of healthy individuals and of patients suffering from autoimmune diseases (Lohse et al., 1996). At around the same time it was suggested that the sole function of a group of suppressor T cells newly identified as $CD4^+CD25^+$ was to inhibit the anti-self aggression of any autoimmune T cells that (presumably owing to an evolutionary mistake) had left the thymus and taken up residence in the periphery (Shevach, 2000; Shevach et al., 2001). It is contrary to Darwinian theory, however, to propose that two cell populations exist in the same organism for the sole purpose of inhibiting each other's activity. Survival of the fittest implies that unwanted features, especially if harmful, will disappear, while beneficial features will be transferred to future generations (Paul, 1988; Herman, 1997; Elliott, 2003). Thus, since all humans possess a similar repertoire of autoimmune cells (Finn et al., 1996; Ria et al., 2001), Darwinian theory would presuppose that these cells have a physiological function.

Theoretically, complete elimination of autoimmune T cells would be the best way to prevent autoimmune disease development, whereas uninhibited autoimmunity would be the best way to counteract neurodegenerative disorders and cancer. A Darwinian resolution of these opposing immunological scenarios might have led, as a compromise between risk and benefit, to the concomitant presence of autoimmune T cells and the regulatory T cells that normally suppress them (Schwartz and Kipnis, 2002). Based on the accumulated information describing the role of autoimmunity in the devastating conditions of cancer (Shimizu et al., 1999; Sakaguchi et al., 2001) and neurodegeneration (Kipnis et al., 2002), it seems unlikely that even the most ardent disciple of Burnet would suggest that complete deletion of autoimmunity favors survival of the fittest. Hence a new theory based on solid data suggests that $CD4^+CD25^+$ regulatory T cells do not exist in a permanently suppressive state that keeps autoimmune T cells unresponsive to self-antigens, but are amenable to modulation by physiological signals that weaken or strengthen their suppressive activity according to need.

45.2.2. Autoimmune T Cells Protect Neurons from Degeneration

Autoimmunity has long been viewed as a destructive process. However, a strong body of evidence provides a new view

whereby autoimmunity is the body's endogenous response to CNS injury, and that its purpose is beneficial. This notion was based on the observation that in rodents, passive transfer of encephalitogenic (disease-inducing) T cells reactive to myelin basic protein (MBP) reduces postinjury neuronal losses.

During the last two decades it has become increasingly clear that different degenerative diseases of the CNS share a number of primary and secondary features (Evert et al., 2000; Rehman, 2000; Hur et al., 2002; Carri et al., 2003). In many such diseases the local microglial response is often viewed as an unwelcome contributor to the disease pathology (Aschner et al., 2002; Koutsilieri et al., 2002; Liu et al., 2002). Recent data suggest, however, that such a view is an oversimplification, and that a well-controlled glial response is beneficial in protecting the affected tissues (Banati et al., 1994; Aschner et al., 2002), whereas malfunctioning glia contribute to the ongoing neurodegenerative process (Teismann et al., 2003). This spread of neuronal damage is caused, at least in part, by compounds which, though normally essential for the survival and function of neurons, become toxic when their physiological concentrations are exceeded. Among the injury-related mechanisms that might underlie the post-traumatic spread of damage are biochemical and metabolic changes in oxygen and glucose utilization, energy state, lipid-dependent enzymes, free radicals, eicosanoids, tissue ions, biogenic amines, endogenous opioids, and excitatory amino acids. These changes cause alterations in cellular homeostasis, excitotoxicity, local production of agents harmful to nerve cells, and a loss of trophic support from targets, all of which result in secondary neuronal loss.

Immune responses in the CNS are relatively restricted, resulting in the status of the CNS as an immune-privileged site (Streilein, 1995). The unique nature of the communication between the CNS and the immune system can be observed, for example, in the dialog between the CNS and T cells. Under normal conditions activated T cells can cross the blood-brain barrier and enter the CNS parenchyma. However, only T cells capable of reacting with CNS antigens seem to persist there (Hickey et al., 1991). Comparative studies of the T-cell response at sites of axotomy in the CNS and the peripheral nervous system (PNS), using T-cell immunocytochemistry, revealed a significantly greater accumulation of endogenous T cells found in injured PNS axons than in injured CNS axons (Moalem et al., 1999a). Moreover, in cases of inflammation, the CNS showed a marked potential for elimination of T cells via apoptosis, whereas such elimination was less effective in the PNS, and was almost absent in other tissues such as muscle and skin (Gold et al., 1997).

In 1999, it was demonstrated that autoimmune T cells directed against myelin basic protein can protect neurons against degeneration after CNS injury (Moalem et al., 1999b).

To verify that this finding was not merely the result of an experimental manipulation but rather a beneficial physiological response to CNS injury, neuronal degeneration after identical injuries was compared in normal mice and mice devoid of T cells (Kipnis et al., 2001; Yoles et al., 2001). Significantly

more degeneration was observed in the nude mice than in the wild type, suggesting that neuroprotection is a physiological, T cell-dependent process (Yoles et al., 2001). To confirm the autoimmune character of this beneficial physiological response, animals were tolerized to myelin antigens at birth. The tolerized animals showed significantly fewer surviving neurons after injury than their matched controls that had been immunized neonatally with an irrelevant (non-myelin) protein (Kipnis et al., 2002).

It had been widely accepted that autoimmune T cells in the periphery are normally kept in a state of tolerance by the suppressive activity of naturally occurring regulatory CD4⁺CD25⁺ T cells (Treg cells) (Thornton and Shevach, 2000), and that elimination or depletion of Treg cells might therefore cause development of an autoimmune disease in susceptible animals (McHugh et al., 2002).

Verification of a new perception of autoimmunity is seen in the experiments in which mice were depleted of Treg cells assuming that such a manipulation would increase the ability to fight off neurodegenerative conditions (Kipnis et al., 2002; Kipnis et al., 2004a). Regardless of the mouse's inherent susceptibility to autoimmune disease, Treg cell depletion resulted in increased neuronal survival (Kipnis et al., 2004b). These and other observations led to propose that the ability to harness a T cell-dependent protective mechanism is controlled by Treg cells, and that the constitutive presence in healthy individuals of both autoimmune T cells and regulatory T cells represents an evolutionary solution to the need for autoimmune T cells for maintenance and repair, with Treg cells acting as a safeguard against the risk of autoimmune disease (Schwartz and Kipnis, 2002). According to these and other results, it was reasonable to assume that weakening of the Treg cell-mediated suppression would benefit both anti-cancer and neuroprotective immunity. It was recently shown that transforming growth factor (TGF)- β sustains the regulatory character of Treg (Fantini et al., 2004; Zheng et al., 2004) cells but no physiological compound has been identified that can weaken Treg. It is plausible that a physiological molecule capable of weakening the activity of Treg cells, at least in cases of CNS injury, must be a brain-derived compound whose half-life is short and whose concentration in the periphery is low.

Among the known neurotransmitters that participate in a stress response, are increased after injury, and are associated with tumors, dopamine seemed to us the most suitable candidate for interaction with Treg cells. Physiological dopamine is increased under stressful conditions (Saha et al., 2001; Vermetten and Bremner, 2002). Its peripheral concentration is low, it is highly unstable in the blood, and it has been shown to participate in neuroimmune dialog (Weihe et al., 1991; Robertson and Jian, 1995; Ilani et al., 2001; Levite et al., 2001; Lemmer et al., 2002). Almost all cells of the immune system, including T cells, bear dopamine receptors (Weihe et al., 1991). Interaction between neurotransmitters and immune cells (e.g. T cells) has been investigated in a whole population of T cells and in a subpopulation of CD4⁺ T cells, but no distinctions were

made in those studies between regulatory and effector (auto-immune) T cells.

Studies of isolated populations of CD4 T cells, revealed that dopamine exerts a direct weakening effect on the suppressive ability of CD4⁺CD25⁺ (Treg) cells (Kipnis et al., 2004b). The receptors that mediate this effect belong to the type-1 family of dopamine receptors (D1R and D5R). These receptors are expressed only weakly, if at all, on effector T cells (Teff cells), but are strongly expressed on Treg cells, allowing preferential action of dopamine on Treg. Short-pulse application of dopamine to Treg significantly decreased the suppressive activity of Treg co-cultured with Teff. The inhibitory effect of dopamine on Treg suppressive activity was manifested in decreased production of interleukin (IL)-10 and TGF- β , which participate in cytokine-mediated suppression. Dopamine was also found to down-regulate CTLA-4, which is expressed constitutively on Treg and is responsible for cell-to-cell contact-mediated suppression. Other catecholamines, such as epinephrine, norepinephrine and serotonin, had no effect on Treg, although they affected Teff and their receptors were found to be expressed by Treg (Kipnis et al., 2004b).

The dopamine-induced weakening of Treg-cell suppressive activity might be considered a first signal in the cascade of events that activates the autoimmune T cells. With the suppression lifted, activation of Teff cells further requires presentation of their specific antigen and of a co-stimulatory molecule by APCs. The availability of antigen is apparently sufficient to maintain homeostasis in the normal healthy CNS, but after an acute injury or under chronic neurodegenerative conditions it appears that antigen availability on its own does not suffice. Thus, in the absence of a mechanism capable of weakening the suppressive effect of Treg cells, the evoked response might not be sufficient to cope with the demands generated by the injury (Schwartz and Kipnis, 2002).

In the case of malignancies, where autoimmunity is required to fight off the cancer, Treg cells interfere with the body's natural propensity to activate a protective mechanism. Depletion of these cells, much as in the case of neurodegenerative conditions, increases the ability to reject tumors (Shimizu et al., 1999). In patients with certain malignancies, dopamine levels in the periphery are increased (Saha et al., 2001). It seems reasonable to suggest that this stress-related compound, possibly in combination with some other compound(s), might be the signal in cancer patients that weakens the Treg-mediated suppressive effect.

Dopamine or its specific D1 agonists have been shown to further block the Treg cell-mediated suppression of Teff cells (Kipnis et al., 2004b), a finding with intriguing implications for therapy. Injection of the D1 agonist SKF-38393, immediately after a traumatic injury, or induction of glutamate neurotoxicity in the mouse CNS, increases neuronal survival. SKF-38393 did not have any effect in mice devoid of T cells, indicating that its beneficial effect in the wild type was not exerted directly on the neurons, but rather via T cells. Since dopamine cannot cross the blood-brain barrier its effect in

wild type animals subjected to injury can be assumed to be peripheral. Treatment with dopamine and its relevant agonists might also be considered for cancer rejection. It was shown that regulatory T cells suppress a spontaneous T cell response to cancer and mice depleted of Treg efficiently reject transplanted tumors.

It should be kept in mind that T cells can do only what T cells can do regardless of their antigenic specificity. Production of cytokines and growth factors from T cells is a matter of their activation and taken within the context of the affected/injured tissue. Antigenic specificity of T cells could be viewed only as a means of homing T cells to a tissue/site in need. Once T cells reach the tissue in need and are reactivated, the antigenic specificity becomes irrelevant to the effector phase (Mizrahi et al., 2002). Therefore, in order to achieve any neuroprotective or other effect in the CNS, it would follow that T cells should be directed to CNS antigens. T cells do not have a way of directly communicating with neurons, as neurons do not express MHC class II molecules. Therefore, two routes of interactions are possible; either through cytokines produced by T cells following activation or through an indirect effect. The indirect effect could be mediated via microglia or astrocytes. Both of these cell types are able to express MHC molecules, whose expression is further increased following injury, thus enabling direct interaction of T cells with microglia (Moalem et al., 1999a). The role of microglia and astrocytes is far beyond what was originally thought. Glial cells do not only serve as glue for neuronal tissue but actively participate in excitation and neural firing and generally contribute to brain plasticity. Microglial cells, resident immune cells in the brain, are able to obtain various phenotypes, depending on activators and context of the tissue. Following injury and under chronic neurodegenerative conditions microglia might serve as a primary source for reactive oxygen species, glutamate, nitric oxide and other cytotoxic compounds (Rutkowski et al., 2000; Penkowa et al., 2003; Rostasy, 2005; Stadelmann et al., 2005). On the other hand, microglia, as well as astrocytes, have the potential to buffer glutamate and produce neuronal growth factors. Studies from our laboratory showed that T cells can affect the phenotype of microglia and switch it towards not only a less destructive but also towards a protective phenotype and even a phenotype that support cell renewal. Following activation of microglia with T cells, in-vitro, glutamate-buffering capacity of microglia is significantly increased, along with production of neuronal growth factors, e.g. BDNF, and there is a reduced production of cytotoxic factors, e.g. TNF-alpha (Shaked et al., 2004; Butovsky et al., 2005a, b; Shaked et al., 2005; Butovsky et al., 2006).

Due to the high trafficking ability of T cells and their ability to penetrate tissues and "talk" with the local antigen-presenting cells, they can serve as mobile mini-factories with an ability to produce growth factors and cytokines upon need and thus maintain the homeostasis of the tissue. Under physiological conditions deviations are minimal and glial cells are able to maintain the homeostasis. Under pathological conditions,

physiological activation of microglia cannot cope with the extreme deviation and thus T cells are required to facilitate glial activity to regain homeostasis. Therefore a dual effect of T cells in brain maintenance is achieved by prevention of a cytotoxic phenotype of glia and boosting of their protective phenotype (Schadlich et al., 1983; Schwartz, 2004; Schwartz and Kipnis, 2005b).

45.2.3. The Mechanism Underlying Protective Autoimmunity

There are many different subpopulations of CD4⁺ T cells, each responsible for a certain type of immune response. Th1 cells, for example, reinforce innate immunity and activate CD8⁺ T cells, whereas Th2 cells recruit and activate B cells. Autoimmune CD4⁺ T cells (Teff) locally boost and control resident microglia and infiltrating blood-borne monocytes, helping them to acquire the ability to fight off degenerative conditions requiring removal of dead cells and cell debris, as well as buffering of toxic compounds without producing inflammation-associated compounds such as tumor-necrosis factor (TNF)- α , NO, or cyclooxygenase (COX)-2 (Levi et al., 1998; Basu et al., 2002; Janabi, 2002; Schwartz, 2003). Thus, according to recent results, the role of CD4⁺ T cells directed against self-antigens (helper T cells, Th) is to activate the innate response, enabling it to recognize that the threat to the tissue is not a harmful organism that it must kill, but as a toxic substance that it must neutralize or eliminate. In addition, the autoimmune T cells, upon encountering their specific antigens presented by antigen-presenting cells at the lesion site, can produce protective compounds such as growth factors and neurotrophins (Hammarberg et al., 2000; Moalem et al., 2000; Gielen et al., 2003). All of these tasks can be accomplished by a well-controlled response of helper T cells. These Th cells, in order to do their job, require local activation by their specific antigens residing in the site of stress. Thus, antigenic specificity apparently dictates the homing of T cells to the site where their local activation can occur. This is consistent with the findings that T cells having the same antigenic specificity are protective against different types of threatening stimuli occurring at the same site, or against different threatening stimuli at different sites occupied by the same immunodominant self-proteins. As a corollary, the same threatening stimulus, if manifested at different sites that do not share common dominant self-antigens, does not benefit from T cells directed against the same antigens.

Studies from several laboratories have shown that T cells patrol the healthy CNS, but do not accumulate there. The recent data suggest that, in the event of an acute injury or chronic neurodegenerative condition, T cells are recruited by and accumulate in the CNS (Hirschberg et al., 1998; Moalem et al., 1999a), where they might rescue neurons from degeneration if the damage caused by the toxic biochemical environment is not yet irreversible; moreover, the recruited T cells will prevent further deterioration. It is also possible that this autoimmune protective mechanism also operates when the

threat to the tissue is from microbial infiltration. In such a case the anti-self response might occur without the individual being cognizant of the response taking place, unless the harnessed autoimmunity gets out of control, in which case its effect is no longer beneficial but destructive, and might result in an autoimmune disease (Dal Canto et al., 2000; Miller et al., 2001). This might be the situation in individuals who are predisposed to autoimmune disease development (Kipnis et al., 2001). According to this theory the pathogenic self-proteins that have been implicated in autoimmune diseases are the very proteins against which a well-controlled T cell response is protective. This might help explain why autoimmune diseases are often attributed to viral infections in the brain. It might also explain the relatively low clinical prevalence of autoimmune diseases and their occurrence mainly in young adults rather than in the elderly population, whereas neurodegenerative diseases and cancer are common and significantly more prevalent in the elderly, in whom the immune system is deteriorating (Linton and Dorshkind, 2004).

45.2.4. The Missing Link—Adaptive Immunity Controls Microglia Phenotype Needed for Survival, Regrowth, and Renewal

It has long been believed that, irrespective of the type or context of an injurious stimulus, microglia show a stereotyped reaction in that they exhibit a predetermined program of executive functions. Experimental evidence supports the notion that some features of the microglial response might indeed originate in a core program of multi-purpose behavior. It should be noted, however, that most of what we know about the diverse activities of microglia emerges from *in-vitro* studies which cannot adequately reflect the complexity of microglial responses *in vivo*. Deprived of their physiological environment and triggered via a single receptor, the *in-vitro* response of isolated microglia is likely to be one-dimensional (Becher et al., 1996; Stalder et al., 1997; Lombardi et al., 1998; Smith et al., 1998; Kloss et al., 2001; Nakajima et al., 2001; He et al., 2002; Saura et al., 2003; Liuzzi et al., 2004; Shin et al., 2004; Vairano et al., 2004; Vegeto et al., 2004). As an example, when activated by bacterial components such as lipopolysaccharide, microglia acquire an inflammatory and cytotoxic phenotype (Lee et al., 1993; Merrill et al., 1993). This emergency scenario, in which the body's fighting force is called upon to attack and kill bacteria, represents only one possible situation involving microglial activation. In contrast to the traditional notion of a stereotyped response, we favor the idea of diversity in microglial behavior. An acquired response that is defined and refined by an ensemble of incoming signals is not a new concept in cell biology. It does, however, represent a departure from the traditional view of microglia.

Danger signals can come from both foreign material (infectious agents) and endogenous sources (damaged cells or tissues, altered molecules, neurotransmitter imbalances).

Endogenous toxicity (the 'enemy within' (Schwartz et al., 2003)) might result from membrane breakdown products, the extracellular presence of cytosolic compounds, abnormally processed or aggregated proteins (such as β -amyloid), or abnormal abundance of transmitters (such as glutamate). It appears that microglia fail to distinguish between external and self-derived enemies, and consequently their response to danger signals from endogenous agents resembles their response to invading microbes.

The microglial phenotype can be shaped by adaptive immunity (Butovsky et al., 2005b; Shaked et al., 2005). The chemoattractive message of inducible microglial chemokines can be altered by a single T-cell cytokine: interferon (IFN)- γ , probably serving a feedback mechanism, alters the blend of chemokines, thereby shifting the preference for leukocyte subpopulations and conceivably affecting the composition of further infiltrates. Adding another piece to the puzzle, the nature and intensity of this response can be controlled by interleukin (IL)-4, a cytokine associated with Th2 cells (Butovsky et al., 2005b).

Thus, even standard responses triggered by established stimuli in simplified *in-vitro* settings show substantial variation when another factor is added. Microglia respond differently to the same stimulus if it co-exists with an additional stimulus, suggesting that they should be viewed as cells that acquire different phenotypes rather than behave stereotypically. Two stimuli can generate different effects, depending on the sequence of exposure: "priming" (preconditioning in which the first stimulus prepares the cell for an enhanced response to the second), negative priming (desensitization), or interference (where the second stimulus exercises a veto effect over an ongoing response to the prior stimulus). The two-signal interplay becomes even more complex when the time interval between the two exposures (manifested as 'memory') varies, as discussed below. This suggests that upon arrival of a modulator the executive functions of microglia can change not only in magnitude but also in quality. Variability of microglial activity is therefore not merely a reflection of stimulus strength or persistence, but is largely determined by the nature and context of the stimulus (Butovsky et al., 2005a, 2006).

In our view, microglia function as local sentinels. Under certain circumstances restricted activation of these stand-by immune cells might occur without being detected. If these sentinels fail to correctly read incoming stress signals, however, they will not develop the phenotype needed to fight off the threat, or alternatively, the cost of fighting off the threat is likely to outweigh the benefit (in terms of death of neighboring neurons). In addition, the outcome of a correct response to a particular signal could be detrimental if the signal itself is misleading. Self-compounds such as aggregated β -amyloid, for example, induce microglia to respond to them as if they were invading microorganisms to be killed. The phenotype utilized for that purpose is characterized by the production of cytotoxic molecules in quantities that the brain cannot tolerate. In addition, microglia that encounter, for example, aggregated β -amyloid fail to express class II major histocom-

patibility complex (MHC-II) molecules, and therefore lack the ability to interact locally with T cells (adaptive immunity) in the way needed for T cell-mediated expression of protective activity against local threats such as oxidative imbalance or cytotoxicity of neurotransmitters. Thus, paradoxically, under such conditions the microglia are precluded from participating in the adaptive immune responses needed to rescue the tissue from the toxicity that they themselves had helped to generate (Shaked et al., 2004, 2005).

Recent studies have shown that an inflammation-associated autotoxic phenotype not only causes neuronal loss but also interferes with neuronal survival, obstructs neurogenesis, and prevents regeneration (Butovsky et al., 2005a, b, 2006). In contrast, microglia that encounter adaptive immunity acquire a phenotype capable of presenting antigens and engaging in dialog with T cells. Such microglia, depending on the nature and amount of T cell-derived cytokines that they encounter, can become activated without producing the potentially cytotoxic cytokine tumor necrosis factor (TNF)- α or can even down-regulate its production. For example, operating via relatively small amounts of IFN- γ , the T-helper (Th)1 cells—classically viewed as pro-inflammatory—can activate microglia to buffer glutamate, a common player in neurodegenerative diseases (Shaked et al., 2005). Likewise, Th2 cells, commonly viewed as anti-inflammatory, by operating via IL-4 can activate microglia to produce insulin-like growth factor (IGF)-I (Butovsky et al., 2005b), known to be associated with cell renewal (Mattson et al., 2004; Varela-Nieto et al., 2004; Shetty et al., 2005; Sonntag et al., 2005; Butovsky et al., 2006). Microglia activated by IFN- γ or IL-4 therefore protect neurons and can support both neurogenesis and oligodendrogenesis (Butovsky et al., 2006).

We maintain that the protective versus destructive dichotomy of microglial effects does not necessarily reflect conflicting or contradictory activities. In normal healthy individuals, these cells stand ready and waiting to perform neural or immune tasks. However, because the CNS has a limited ability of the to tolerate any deviation from homeostasis, even defensive activity on the part of activated microglia can exacerbate a chaotic situation rather than resolve it.

Strategies for preventing overshooting of microglial reactions can be based on pharmacology, by employing selective suppression of undesirable activities while still permitting other executive functions to be performed. An alternative approach of recruiting T cells of a certain phenotype directed against weak agonists of self-antigens, might result in immunomodulation. Examples of such antigens are altered peptide ligands or the synthetic oligopeptide copolymer 1 (Cop-1) (Teitelbaum et al., 1997; Sela, 1999, 2000). By the use of such antigens for vaccination in a context of neurodegenerative conditions, it was possible—irrespective of the primary risk factor—to boost activity in a well-controlled way (Kipnis et al., 2000; Schori et al., 2001; Schwartz, 2001b; Schwartz and Kipnis, 2005a). Paralysis of microglia can be helpful within an experimental setting of a disease model. However, global

depletion of microglia for extended periods might impair rather than preserve the structure and function of the CNS.

45.3. Development of Therapeutic Vaccinations

Any immune manipulation, which activates the immune system to induce a well-controlled increase in the likelihood that relevant T cells will home to a site of injury site, can be expected to be beneficial. Three major approaches could be considered: immunization with self-antigen agonists, induction of lymphopenia or functional inactivation of naturally occurring regulatory CD4⁺CD25⁺ T cells.

45.3.1. Immune-Based Vaccination for Neurodegenerative Diseases

45.3.1.1. *Copolymer-1 (Glatiramer acetate, CA)*

Recognizing that T cells are needed for assisting CNS in fighting off neurodegenerative conditions have prompted us to search for safe ways to do so without imposing the risk of developing autoimmune diseases. Data accumulated over the last decade has raised several options, including local transplantation of specially activated macrophages in cases of acute insult. In other situations of either chronic or acute neurodegeneration, the choice depends on the therapeutic window and the condition of the tissue (the critical issue being the bias of the microglia). In searching for active vaccination we considered using agonists of self-antigens. Such agonists can activate a response that weakly cross-reacts with the resident self-antigens. One such antigen is the copolymer glatiramer acetate, known as Cop-1, which is safely used daily for treating multiple sclerosis. Yet, for neuroprotection in cases of noninflammatory neurodegenerative diseases the outcome was critically affected by the dosing, regimen and the choice of the carrier (adjuvant). In the case of animal model of ALS, the use of GA emulsified in complete Freund's adjuvant was beneficial, yet adjuvant-free GA was not found to be effective in any of the tested regimens (Haenggeli et al. 2007) and its daily administration was found to be destructive in female ALS mice (Bukshpan et al., unpublished observations). In a model of glaucoma, weekly or monthly injections of adjuvant-free GA were found to be beneficial, but not daily injections (Bakalash et al. 2005). In an animal model of Alzheimer's disease, a weekly injection was found to be beneficial (Butovsky et al. 2006b). Yet translating it into a human therapy requires careful determination of the regimen, which critically determines the T-cell phenotype (Th1, Th2, Treg); and thus, the clinical outcome.

45.3.1.2. *Lymphopenia*

Induction of lymphopenia significantly increases immunoreactivity towards cancer-specific proteins and efficiently sup-

presses cancer (Dummer et al., 2002). A sudden drop in the pool of peripheral T lymphocytes stimulates their homeostasis-driven proliferation in order to restore the pool. In response to the stimulus of lymphopenia, naïve peripheral T cells proliferate and acquire a phenotype reminiscent of memory T cells (Ma et al., 2003). The induced proliferation predisposes the individual to development of an autoimmune response, since under lymphopenic conditions T cells can proliferate upon interaction with MHC-II molecules alone, with no need for a co-stimulatory signal (Sara et al., 1999; Gudmundsdottir and Turka, 2001; Elflein et al., 2003). If at the time of lymphopenia induction the body undergoes stress and consequently certain self-antigens are exposed (e.g., antigens related to tissue injury or cancer), an autoimmune response to those antigens will occur, resulting in a high overall incidence of the proliferation of the relevant T lymphocytes (Gelinas and Martinoli, 2002). In rodents suffering from acute or chronic neurodegenerative conditions, induction of lymphopenia significantly benefits post-injury neuronal survival (Kipnis et al., 2004b). Lymphopenia and the subsequent homeostatic proliferation can be induced in a number of ways, the most clinically relevant being low-dose irradiation of the lymphoid organs. As a result of the lymphopenia, T cells proliferate and become activated. They patrol the body, and their patrol route includes the CNS. On reaching the lesion site, and after being activated by the resident cells that present self-antigens in the MHC-II groove, these lymphopenia-derived T cells perform their effector functions, similarly to T cells obtained by immunization with self- or altered self-proteins (Kipnis et al., 2004a).

45.3.1.3. *Attenuation of Regulatory T Cell Network*

Since the aim is to achieve activation of T cells that cross-react with self-antigens at the site of injury, this can also be done by weakening the naturally occurring Treg cells. In an experimental context, nude mice (devoid of mature T cells) repopulated with a T cell population that did not contain the Treg-cell subpopulation (Kipnis et al., 2002) showed better recovery from a CNS insult than wild-type mice of the same strain. For clinical use, however, what is needed is a reagent that will weaken Treg cells. Dopamine, as mentioned earlier, was found to weaken both the activity and reduce the trafficking of Treg cells (Kipnis et al., 2004b). It is possible that dopamine represents a family of physiological compounds capable of controlling Treg-cell activity, therefore allowing speedy recruitment of the relevant autoimmune T cells. Development of synthetic compounds that can reproduce the dopamine effect is another apparently feasible approach in which a common immune-based therapy could be used to fight off neurodegenerative diseases, irrespective of etiology. Although such compounds might weaken Treg cells nonselectively (i.e., regardless of their antigenic specificity), the subsequently evoked autoimmunity will be restricted to CD4⁺ cells that encounter their relevant antigens, and will consequently be associated with the site under stress.

Summary

Harnessing the immune system in a well-controlled way might be the therapy of choice for neurodegenerative disorders. As long as the integrity of the immune system is maintained and neurotransmitter imbalance in the brain is within the remediable capacity of the immune system, homeostasis remains intact and the integrity of brain performance is preserved. According to this view, therefore, the widening age-related gap between deteriorating immunity and risk factors for diseases can be narrowed by appropriate activation of the immune system.

Review Questions/Problems

1. Absence of macrophages increases the rate of Wallerian degeneration

YES/NO/UNRESOLVED

2. Lack of neuroprotection in thymectomized rats points to the role of naturally occurring regulatory CD4⁺CD25⁺ T cells in endogenous neuroprotection

YES/NO/UNRESOLVED

3. Tova cells are not protective following CNS injury but will be protective following PNS injury

YES/NO/UNRESOLVED

4. T cell specific to NoGo protein might induce neuroprotection in injured CNS

YES/NO/UNRESOLVED

5. Absence of macrophages improves neuronal survival following PNS injury

YES/NO/UNRESOLVED

6. Optic-nerve activated macrophages are better phagocytes than sciatic-nerve activated macrophages

YES/NO/UNRESOLVED

7. Lymphatic drainage from the CNS is unique compared to lymphatic drainage from other tissues

YES/NO/UNRESOLVED

8. GAP43 is a good marker for sprouting

YES/NO/UNRESOLVED

9. Neuroprotection and regeneration are similar processes driven by different cell types

YES/NO/UNRESOLVED

10. Perivascular macrophages are important “partners” in T cell-CNS interaction

YES/NO/UNRESOLVED

11. **Prompt autoimmune response to injury will induce neuroprotection only if this response is tightly controlled.**

YES/NO/UNRESOLVED

12. **Survival of neurons in the injured CNS is an outcome, at least in part, of protective immune response and a destructive local effect of physiological compounds that exceed their normal concentration.**

YES/NO/UNRESOLVED

13. **Only EAE-inducing TMBP cells confer neuroprotection following injury**

YES/NO/UNRESOLVED

14. **T cell specific to NoGo might induce neuroprotection in injured CNS**

YES/NO/UNRESOLVED

15. **Autoimmune T cell-based therapy can be easily combined with methylprednisolone**

YES/NO/UNRESOLVED

16. **Which one of the following statements is the most unlikely?**

- Dopamine may affect CD4⁺ T cells
- Dopamine may affect Treg cells
- Treatment with Dopamine might exacerbate cancer
- Treatment with Dopamine might exacerbate autoimmune disease

17. **Wild type Balb/c mice were injected with autologous carcinoma cells. One group was treated with Dopamine and the other with PBS. Mice are euthanized when cancer reaches 2 cm in size. The plot of survival of mice as a function of time is presented bellow. Which of the following statements is correct?**

- Group 1 was injected with PBS and group 2 with Dopamine
- Group 1 was injected with Dopamine and group 2 with PBS
- Additional information is required to address this question
- None of the above

18. **Multiple sclerosis patient was treated with a new cellular therapy – activated CD4⁺ T cells from this patient were isolated (based on the selection for CD25⁺), anergized in-vitro on immature dendritic cells and returned to the patient's blood stream. This patient has also colon cancer. Which one of the following statements is the most likely?**

- The treatment may exacerbate the ongoing MS disease
- The treatment may exacerbate the ongoing colon cancer
- The treatment will not affect any of the conditions
- The treatment will benefit both diseases

19. **Neuroimmunology primarily deals with:**

- Autoimmune inflammations in the brain
- Autoimmune inflammations in the injured brain
- Inflammatory pain
- The effect of mood on activation of T lymphocytes
- All of the above

20. **Patient was treated with Copaxone for multiple sclerosis and has developed breast cancer. Doctors analyzed the blood samples and found an increase in regulatory T cell numbers based on CD25 and Foxp3 markers. The suggestion made by doctors was that Copaxone induces regulatory T cells and this may lead to cancer development. Which of the comments bellow is FALSE.**

- Doctors might be right
- Doctors did not review the recent literature on Foxp3 in human Treg
- Only if these cells did not produce IL-2 they could be considered as Treg cells
- The suppressive activity of these cells in-vitro should be examined before addressing them a suppressor function
- All of the above

Adjuvants

Sam Sanderson

Keywords Adjuvant; Antigen; C5A; C5a agonist; Complement system; Immunomodulator; Molecular adjuvant; Vehicle

46.1. Introduction

A prominent feature that underscores the current era of vaccinology is the ability to generate a huge variety of antigens (Ag) by various synthetic chemistry and genetic engineering techniques. As a result, Ags now can be produced rapidly and in large quantities with well-defined structures and in highly purified forms—desirable attributes for their use in vaccines intended to generate Ag-specific immune responses in a diverse population. Unfortunately, the routine use of these Ags as integral components of vaccines is encumbered by their inherent lack of immunogenicity. Such vaccines, therefore, require the use of adjuvants in order to potentiate and focus the immune response to the Ag so that optimal immune outcome can be achieved. Thus, the discovery and development of new adjuvants is of growing importance to the design of vaccines capable of meeting the modern threats posed to human and animal populations by new or resurgent infectious and non-infectious diseases.

This chapter will highlight recent trends in the development of novel adjuvants and, to the extent to which it is known, their immunologic mechanisms. A particular emphasis will be placed on those adjuvants composed of single molecular entities, the so called molecular adjuvants.

46.2. General Adjuvants: Vehicles and Immunomodulators

An adjuvant is any substance or any formulation of substances that enhances an immune response to an Ag. As a general rule, adjuvants fall into two major categories, vehicles and immunomodulators (Van Regenmortel, 1997).

Vehicles are those adjuvants that help carry Ags to and retain them in proximity to lymphocytes and other auxiliary

immune cells, particularly antigen presenting cells (APC), within various lymphoid tissues. Indeed, it is this “depot” effect that is the defining mechanism of vehicle adjuvants. Classic examples of vehicles include liposomes, emulsions, proteosomes, and immunostimulating complexes (ISCOM) (Crouch et al., 2005). Typically, the final vaccine formulation is the Ag contained within the vehicle. Other examples of vaccines that utilize vehicles include formulations in which the Ag is covalently linked to bioadhesive microparticles such as poly(D,L-lactide-coglycolide (PLGA) (Diwan et al., 2004), nanoparticles, or adsorbed on the surface of carriers such as calcium and aluminum salts (phosphate or hydroxide), particularly alum, which is the only adjuvant approved for human use (Olive et al., 2001).

Immunomodulators are adjuvants defined by their ability to activate APCs and/or lymphocytes. Typically, this activation is characterized by the adjuvant-induced release of cytokines from lymphocytes and other auxiliary immune cells. Examples of immunomodulators include muramyl-dipeptide (MDP), monophosphoryl lipid A (MPL) (Ulrich and Myers, 1995), lipopoly-saccharide (LPS) (Johnson et al., 1956), bacterial cell membranes (Muhlradt et al., 1998), certain components of the complement system (Dempsey et al., 1996; Jacquier-Sarlin et al., 1995), cytokines (Afonso et al., 1994; Kurzawa et al., 1998), and oligonucleotide mimics of bacterial DNA. The typical vaccine formulation is one in which the Ag is admixed with the immunomodulator. Variations on this theme include those in which the Ag is covalently linked to the immunomodulator with the rationale that elements of the generalized immune response invoked by the adjuvant might be more directed to the Ag. Some examples of this approach include the incorporation of lipids, lipopolysaccharides, and lipoamino acids into peptide Ags by synthetic methods (Metzger et al., 1991; Defoort et al., 1992; Martinon et al., 1992; Wiesmuller et al., 1992; Olive et al., 2001) and the genetic fusion of chemokines/cytokines to protein Ags (Biragyn et al., 1999).

It should be pointed out that this classification of adjuvants is based more on historical observations than on strict

mechanisms of action. In fact, there are several examples of adjuvants belonging to the vehicle family that act as immunomodulators. A noteworthy example of this is the saponins, which are extracted from the plant *Quillaja saponaria* and are used to create emulsions into which Ags are added. Over the years, a variety of chemical modifications of saponins have been used as adjuvants and all appear to stimulate the release of various T helper 1 (Th1) and T helper 2 (Th2) cytokines in addition to their vehicle-like mode of action (Shi et al., 2005).

Finally, there are many examples of vaccine formulations in which individual adjuvants are used in combination with others as a way of optimizing immune efficiency and outcome. Despite the current emphasis placed on evaluating the wide variety of adjuvants in experimental use today and the myriad of possible combinations and formulations, no particular adjuvant or adjuvant system has emerged as an ideal product. Also, given the variation within a data set in which adjuvants are employed, it appears that the effectiveness of an adjuvant or adjuvant system is best evaluated on a case-by-case basis.

46.3. Present-Day Adjuvants in Human and Animal Applications: General Mechanism of Action

As stated above, the principal objective for the use of an adjuvant in a vaccine is to potentiate immune response to an Ag of minimal immunogenicity. How this potentiation is achieved varies from adjuvant to adjuvant and in many cases, the precise mechanism of action is unknown. However, as a rule, immune potentiation is accomplished by the ability of the adjuvant to induce a variety of non-specific activities within the innate arm of the immune system. Once activated, the innate branch of immunity, particularly the complement system, orchestrates the various humoral and cell-mediated responses that operate within and between the innate and acquired arms. The result is a generalized activation and potentiation of the immune system in response to the adjuvant with the hope that this generalized immune priming will allow for a more effective processing and recognition of the Ag contained within the vaccine.

The manner by which an adjuvant induces this immune priming emanates from the exquisite sensitivity of the mammalian immune system to detect the presence of bacteria and bacterial components and respond accordingly in a rapid and vigorous manner. The initial response to these bacterial signals is largely a function of the innate branch of the immune system, which has evolved under continual selective pressure from pathogenic bacteria and other disease-causing microorganisms. It is not surprising, therefore, that the majority of adjuvants in use today are composed of various molecules, components, and structures derived from bacteria. The use of these adjuvants in vaccines, therefore, provides the bacterial signals to which the innate arm of the immune system

vigorously reacts, which results in the priming/potentiation of the immune system.

However, this rapid and vigorous innate response to the bacteria-like signals induced by such adjuvants can result in an overly aggressive and misdirected immune response that is accompanied by undesirable side-effects such as anaphylaxis, fever, injection site granulomas or rashes, and local or systemic inflammation. Another drawback is that the adjuvant tends to induce a generalized immune response with little immune specificity directed to the Ag of interest. Also, immunity that might be directed to the Ag can be masked due to the magnitude of the innate response to the adjuvant. In an attempt to overcome these drawbacks, there is a vigorous and concerted research effort worldwide to develop modifications of bacterial-derived adjuvants such that they retain their ability to induce innate responses to bacterial signals, but minimize or eliminate the deleterious inflammatory side-effects that can accompany such signals. Notable examples of such efforts include the many chemical and structural modifications developed and tested on MPL (Ulrich and Myers, 1995) and the saponins (Shi et al., 2005).

46.4. Molecular Adjuvants

46.4.1. Definition

The need for an adjuvant capable of inducing a robust *and* Ag-specific immune response accompanied with minimal inflammatory side-effects has given rise to a new class of adjuvants, which have come to be known as molecular adjuvants (Dempsey et al., 1996). The rationale for a molecular adjuvant is based on the notion that a single, well-defined and well-characterized molecular entity might be better in inducing an immune response more directed to the Ag with fewer non-specific side effects, particularly when the Ag is attached directly to the molecular adjuvant. Thus, a molecular adjuvant can be defined as a single molecular entity that targets an Ag to the cells of the immune system responsible for Ag processing and presentation and/or activates specific pathways of Ag processing and presentation within these cells.

46.4.2. Complement

As described above, “traditional” adjuvants typically are derived from bacterial components in order to provide the bacteria signals necessary for the activation and potentiation of the innate arm of the immune system. One of the first components of innate immunity that becomes activated in response to these bacterial signals is the complement system.

Complement is a plasma system comprised of interrelated proteases arranged in a cascade fashion that becomes activated in response to bacterial signals and Ags associated with bacteria. The role of complement is twofold: 1) to serve as an initial, first line of defense to invading microorganisms and 2) to enhance systemic host defense by activating and orchestrating the

various humoral and cell-mediated responses within the acquired and innate arms of the immune system necessary for the effective elimination of the microorganism.

The “first line of defense” is accomplished through the generation of the membrane attack complex (MAC), which is assembled at the end of the complement cascade from the components generated by the proteolytic steps along the cascade. The MAC is directly involved in lysing the membranes of foreign microorganisms.

Secondly, the various humoral and cell-mediated responses operating at the interface of the innate and acquired arms of the immune system are activated and coordinated by pharmacologically active components that are released at certain steps along the complement cascade. These proteolytic byproducts, which are independent of the components that comprise the MAC, induce the various humoral and cell-mediated aspects of the innate and acquired arms of immunity, all of which are necessary for the concerted elimination of the microorganism.

Principally because of this latter reason, these pharmacologically active components of complement are attractive as molecular adjuvants. This is because their use has the potential of enhancing specific pathways of the innate and acquired immune processing and subsequent recognition of an Ag as opposed to the broader and less Ag-focused activation of the innate system in response to bacterial signals that come from of adjuvants derived from bacterial components.

46.4.3. Complement-Derived Molecular Adjuvants

Certain components of complement have been used as molecular adjuvants to enhance Ag-specific immune responses to model Ags. Components of complement that have been used as molecular adjuvants include C3b, C4b (Arvieux et al., 1988; Jacquier-Sarlin et al., 1995), and C3d (Dempsey et al., 1996). These components were chosen primarily for their opsonic properties; i.e., their ability to bind to and coat the surface of a microorganism rendering it more susceptible to immune cell uptake via phagocytosis. The rationale, therefore, was that an Ag covalently attached to these complement fragments similarly would be rendered more susceptible for uptake by APCs and, consequently, would be more effectively processed and presented by the APC. In all cases, the immunogenicity of the model Ag in the Ag-complement vaccine complex was markedly enhanced relative to the Ag alone, suggesting that the complement fragment acted as a molecular adjuvant by enhancing Ag uptake by APCs and, in turn, the ability of the APC to process and present the Ag. Although the precise mechanism by which these molecular adjuvants enhance uptake, processing, and presentation is not fully understood, these studies clearly demonstrate the immunologic potential of using complement components as molecular adjuvants in the design of vaccines.

46.4.4. The Anaphylatoxins

An important group of pharmacologically active byproducts of complement activation are the anaphylatoxins C3a, C4a, and C5a, which are small (74–76 residue) fragments cleaved from the larger, parent complement components C3, C4, and C5, respectively. The principal roles of the anaphylatoxins are to recruit inflammatory cells and lymphocytes to sites of tissue injury and infection and to then activate these cells' various effector responses once recruited (Hugli, 1981). However, the anaphylatoxins play important roles in the activation and regulation of humoral and cell-mediated responses to Ags due to their ability to modulate various humoral and cell-mediated activities between the innate and acquired arms of the immune system (Dempsey et al., 1996; Mastellos et al., 2005; Morgan, 1986). Consequently, the anaphylatoxins are attractive as molecular adjuvants, which may be capable of invoking Ag-specific humoral and/or cell-mediated immune responses.

Unfortunately, the anaphylatoxins are also potent inflammatory mediators and their use as molecular adjuvants would surely be accompanied by local and/or systemic inflammatory side effects. Also, under certain conditions, the anaphylatoxins appear to downregulate immune function. For example, C3a has been regarded as a general suppressor of immune function and has been shown to downregulate certain Th2-mediated responses to Ags (Kawamoto et al., 2004; Morgan, 1986). Thus, while the anaphylatoxins have desirable immune stimulatory activities that make them attractive for use as molecular adjuvants, they carry with them the potential for adverse inflammatory side effects and immune downregulation. In order for an anaphylatoxin to be used as a molecular adjuvant, therefore, its immune stimulatory activities must be enhanced at the expense of its inflammatory activities and any tendency to downregulate immune response.

46.4.5. Immunostimulatory and Inflammatory Properties of C5a

Of the anaphylatoxins, C5a has many immune stimulatory activities that are particularly attractive for its use as a molecular adjuvant. For example, C5a has been shown to enhance Ag-specific and mitogen-induced antibody responses (Goodman et al., 1982; Morgan et al., 1983), Ag-induced T lymphocyte proliferation (Morgan et al., 1983), MHC-restricted T cell proliferation via primary and autologous mixed lymphocyte reactions (Goodman et al., 1982; Morgan et al., 1983; Montz et al., 1990), and the tumoricidal activity of monocytes (Hogan et al., 1989). Also, C5a directly and/or indirectly induces the synthesis and release of a variety of immunoregulatory cytokines from monocytes and macrophages including IL-1 (Okusawa et al., 1987; Goodman et al., 1982; Wetsel, 1995; Buchner et al., 1995), IL-6 (Scholz et al., 1990; Gasque et al., 1995), IL-8 (Ember et al., 1994), IL-12 (Floreani, A., Heires, A., and Sanderson, S.D. personal communication) and TNF α (E.L.

Morgan, personal communication) as well as IL-1 β , IL-6, IL-8, IL-12, TNF α , and IFN γ from human dendritic cells (E.L. Morgan, personal communication).

Being an anaphylatoxin, however, C5a also expresses many proinflammatory activities. These include its potent chemotactic activities for the recruitment of inflammatory cells to sites of tissue injury and infection (Shin et al., 1968), its ability to induce smooth muscle contraction (Hugli et al., 1987), increase vascular permeability (Hugli and Muller-Eberhard, 1978; Hugli, 1981, 1990), and induce the release of a variety of secondary inflammatory mediators such as histamine, lysosomal enzymes, and vasoactive eicosanoids from responsive cells such as mast cells, neutrophils, eosinophils, and macrophages (Drapeau et al., 1993; Johnson et al., 1975; Goldstein and Weissmann, 1974; Schorlemmer et al., 1976; Lundberg et al., 1987).

These biologic responses, inflammation and immunomodulation, are induced by the binding of C5a to its specific, high affinity receptor (C5aR, CD88) that is expressed on the surface of the C5a-responsive cell(s). Traditionally, C5aR expression has been viewed as being limited to cells of myeloid origin such as neutrophils, monocytes, mast cells, and eosinophils (Wetsel, 1995). However, it is now known that a variety of human cells of nonmyeloid origin express C5aRs. These include hepatocytes (Buchner et al., 1995), astrocytes (Gasque et al., 1995), bronchial epithelial cells (Floreani et al., 1998), epithelial cells of the gut and kidney (Wetsel, 1995), and osteoblasts (Pobanz et al., 2000). The presence of C5aRs on these cells poses interesting questions about the nature of the C5a-mediated response and its role in the function of these cells under normal and aberrant physiologic conditions and is the focus of an active research program in our and several other laboratories.

Because of its proinflammatory properties, C5a has been implicated in a number of inflammatory disorders such as rheumatoid arthritis (Jose et al., 1990), adult respiratory distress syndrome (Till et al., 1982; Mulligan et al., 1996), gingivitis (Wingrove et al., 1992), systemic lupus erythematosus (Hopkins et al., 1988) psoriasis (Bergh et al., 1993), reperfusion injury (Amsterdam et al., 1995), and gram-negative bacterial sepsis (Smedegard et al., 1989). This pathogenic involvement has provided the motivation for the development of C5a/C5aR antagonists to inhibit these C5a-mediated inflammatory disorders (Kontekis et al., 1994; Finch et al., 1999).

As the inflammatory properties of C5a have been the motivation behind the development of C5a antagonists, so too have the immunostimulatory properties of C5a been the motivating factor for the development of agonists of C5a that can be used as surrogates of the natural factor for enhancing humoral and cell-mediated immune responses; i.e., as a molecular adjuvant. Using such agonists of C5a as a molecular adjuvant, however, requires developing response-selective agonists that are capable of invoking C5a-like immunostimulatory properties at the expense of C5a-like inflammatory properties.

46.4.6. C5a: Structure-Function Considerations

Human C5a is a 74-residue glycopolypeptide that is comprised of two important structural and functional domains. The first is the well-ordered N-terminal core domain comprised of residue 1–63, which is primarily involved in the recognition and binding of C5aRs (Mollison et al., 1989; Zuiderweg et al., 1989). The second is the C-terminal domain, residues 64–74, which extends from the N-terminal core as a finger-like projection. C5a_{65–74} (ISHKDMQLGR) is a region of considerable backbone flexibility and poorly-defined structure (Zuiderweg et al., 1989), yet the proinflammatory and immunostimulatory activities characteristic of the entire C5a polypeptide reside in this small C-terminal stretch (Ember et al., 1994, 1992; Morgan et al., 1992). Thus, an early objective in developing agonists or antagonists of C5a was to synthetically manipulate this region of C5a with the goal of generating a peptide-based ligand that would either bind the C5aR with high affinity but not transducer a biological signal (a C5a antagonist) or would bind and modulate the C5aR in such a way that only a limited or specific signal transduction event(s) such as immunostimulation would be activated (a response-selective C5a agonist).

Flexibility in the C-terminal, effector region of C5a (C5a_{65–74} or ISHKDMQLGR) is a dominant feature of natural C5a (Mollison et al., 1989; Zuiderweg et al., 1989). It may be that this flexibility allows the C5aR the ability to induce a unique conformation in this region of the C5a ligand that is conducive to the expression of biologic activity characteristic of that particular C5aR-bearing cell. It may be, in fact, that a biologically active conformation in this effector region of C5a responsible for activity in one type of C5aR-bearing cell may not be the ideal conformation for the expression of activity in another. This suggests therefore, that by employing a synthetic strategy in which the flexibility in this effector region of C5a is restricted, one might bias certain conformational features that are important for the expression of certain types of C5aR-mediated activities; i.e., a response-selective agonist. Such a specific and stabilized conformation, when presented to the C5aR, would be more likely to interact with those C5aRs that are capable of accommodating this particular conformation.

46.4.7. Conformationally Restricted Analogues of C5a_{65–74}

Over the years, our laboratory has generated a library of analogues of C5a_{65–74} in which backbone flexibility was restricted by certain amino acid substitutions. This was done with the goal of biasing certain conformational features that might be helpful in the search for biologically relevant conformations responsible for the induction of C5a-like immunostimulatory activities versus those responsible for C5a-like inflammation.

Backbone flexibility was restricted by introducing three principal types of residue substitutions within C5a₆₅₋₇₄: 1) Pro substitutions to restrict ϕ angle flexibility and to narrow the range of sterically allowed backbone conformations in the pre-proline residue (Hruby and Nikiforovich, 1991), 2) Ala substitutions to evaluate the biological importance of the side-chains in the peptide, and 3) D-residue substitutions to assess the contribution of stereoisomeric arrangements. The use of such peptide modifications has an additional advantage in that Pro, Ala, and D-residues occupy well-defined regions of sterically-allowed Ramachandran space (Hruby and Nikiforovich, 1991). Thus, an evaluation of the changes made in the biological activity of these conformationally restricted analogues of C5a₆₅₋₇₄ can provide information about the specific types of backbone conformation features that are important to specific types of biological activity.

Using this approach of biasing backbone conformation, we showed that one peptide from this library, C5a₆₅₋₇₄Y65,F67,P69,P71,D-Ala73 or YSFKPMPLaR exhibited about 10% of the potency of natural C5a for its ability to induce the release of spasmogenic eicosanoids from tissue resident macrophages in human umbilical artery, but only about 0.1% of C5a activity in its ability to induce the release of β -glucuronidase from human neutrophils (Finch et al., 1997). This difference in biological potency was reflected by a corresponding difference in binding affinity to the C5aRs expressed on these cells: $IC_{50} = 0.2 \mu M$ in rat peritoneal macrophages compared to $10 \mu M$ in human neutrophils (Finch et al., 1997, Vogen et al., 2001). This difference has been expressed as a function of the relative selectivity of YSFKPMPLaR in interacting with C5aRs on macrophages relative to C5aRs on neutrophils: selectivity = $\text{antilog}[\text{pD}_2\text{macrophage activity} - \text{pD}_2\text{neutrophil activity}]$. This measure of selectivity showed that YSFKPMPLaR was significantly more potent/selective in inducing eicosanoid release from C5aR-bearing macrophages than enzyme release from C5aR-bearing neutrophils relative to natural C5a and several other analogues less conformationally biased than YSFKPMPLaR (Finch et al., 1997). Another noteworthy property of YSFKPMPLaR, but not natural C5a or more flexible analogues of C5a₆₅₋₇₄, was the increased stability of the biologically important C-terminal Arg residue to proteolytic cleavage by serum carboxypeptidases (Kawatsu et al., 1996). The presence of this C-terminal Arg residue, particularly in small peptide agonists of C5a, is essential for the expression of full biological activity and its retention *in vivo* is an important consideration in the design of response-selective agonists of C5a for therapeutic use.

Nuclear Magnetic Resonance (NMR) analysis (Vogen et al., 1999b) of YSFKPMPLaR in water indicated the presence of extended, polyproline II (P_{II}) backbone conformation extending through residues 68–70/71 (KPM/P), which was expected from the influence of Pro at position 69 (Hruby and Nikiforovich, 1991). The C-terminal region (PLaR) adopted a distorted type II β -turn or a type II/V β -turn. In the type II/V β -turn, Leu72 exhibited a conformation characteristic of

a type II β -turn, whereas D-Ala73 exhibited a conformation characteristic of a type V β -turn. Furthermore, an overlapping inverse γ -turn involving residues LaR was observed within the type II/V β -turn. This combination of conformational features in a peptide of only ten residues is highly unusual and underscores the unique topography that can be introduced in these C-terminal analogues of C5a and their potential for therapeutic use.

Indeed, the increase in potency/selectivity expressed by YSFKPMPLaR for eicosanoid release from macrophages versus enzyme release from neutrophils is attributed to the unique conformational features expressed in YSFKPMPLaR and the fact that they appear to be well accommodated by C5aRs on macrophages, but not by C5aRs on neutrophils. Why this is the case is not understood and it remains to be determined whether this difference might emanate from the ability of YSFKPMPLaR to distinguish between two different subtypes of C5aRs expressed on these two cell types. These studies represent only a beginning in understanding the relationship between structure and function of these C5a agonists and considerable work is required to identify and relate a specific topochemical feature of the agonist to a specific C5aR-mediated biological response(s). Nevertheless, the structure-function information provided by these conformationally biased decapeptide agonists of C5a support the development of highly response-selective agonists of C5a and offers some insight as to the types of backbone conformations that may related to selective activation of the C5aR expressed on different C5aR-bearing cells, particularly C5aR-bearing cells of the immune system (Taylor et al., 2001).

46.4.8. YSFKPMPLaR as a Molecular Adjuvant

YSFKPMPLaR has been used as a molecular adjuvant in *in vivo* studies designed to evaluate its effectiveness as a C5a surrogate capable of inducing Ag-specific humoral and cell-mediated responses to various B and T cell epitopes. This was approached by synthesizing the epitope directly onto the N-terminal end of YSFKPMPLaR thus leaving the C5a agonist moiety of the construct free to interact with C5aRs expressed on APCs. It was hypothesized that the YSFKPMPLaR moiety would carry the epitope to and activate the APC in a manner similar to natural C5a via interaction with surface expressed C5aRs for which YSFKPMPLaR has high affinity and selectivity (Tempero et al., 1997). YSFKPMPLaR, like natural C5a, would activate APCs via the synthesis and/or release of Th1 and Th2 cytokines. Following this APC activation, the C5aR/ligand complex would internalize and carry the attached epitope into intracellular Ag processing pathways where it associates with major histocompatibility complex (MHC) determinants for expression on the APC surface. Of our library of conformationally biased C5a agonists, YSFKPMPLaR was the ideal choice for use as a molecular adjuvant because of its enhanced potency/selectivity for C5aR-bearing APCs such as macrophages versus neutrophils

and the stability of its crucial C-terminal Arg residue to cleavage by carboxypeptidases.

46.4.8.1. Generation of Ag-Specific Antibody Responses

In one study (Tempero et al., 1997) YSFKPMPLaR was used to induce Ag-specific antibody (Ab) responses to a B cell epitope derived from the juxtamembrane region of human mucin type 1 glycoprotein (MUC1). A C5a-active construct was generated by covalently attaching the MUC1 epitope (*YKQGGFLGL*) to the N-terminus of YSFKPMPLaR (*YKQGGFLGLYSFKPMPLaR*). This construct was shown to be a full agonist of natural C5a and expressed the same response-selective properties exhibited by YSFKPMPLaR alone. A C5a-inactive construct was generated by attaching the MUC1 epitope to the biologically important C-terminal end of YSFKPMPLaR (*YSFKPMPLaRYKQGGFLGL*). This construct retains the same amino acid composition as the C5a-active construct but is devoid of C5a-like activities and, therefore, serves as an ideal negative control to the C5a-active construct.

C57BL6 and BALB/c mice were immunized with the following constructs: 1) YSFKPMPLaR, 2) *YKQGGFLGL*, 3) YSFKPMPLaR + *YKQGGFLGL*, 4) *YKQGGFLGLYSFKPMPLaR*, and 5) YSFKPMPLaR*YKQGGFLGL*. Mice were immunized via intraperitoneal injection of a 100 µl solution containing 100 µg of the peptide. Mice were boosted at 2-week intervals and sera obtained for analysis after 6 weeks. Another set of mice was immunized under identical conditions, but with a more traditional construct of the MUC1 epitope attached to the carrier protein keyhole limpet hemocyanin (KLH). In order to effectively evaluate immune outcome from the peptide-based and KLH-based vaccine constructs, immunizations were performed in the presence of MPL adjuvant so that the KLH construct was given a chance to induce immune response under more typical immunization conditions.

High Ab titers specific for the MUC1 epitope were observed only in mice immunized with the C5a-active construct, *YKQGGFLGLYSFKPMPLaR* and the epitope-KLH construct. These anti-epitope Abs were shown to cross react with rhMUC1 protein expressed on the surface of a transfected pancreatic cell line (Panc-1 M1F.15). This indicates that the anti-*YKQGGFLGL* Abs appear to recognize the *YKQGGFLGL* epitope within intact whole MUC1 protein.

The isotypes of the Abs generated by the molecular adjuvant-containing construct were IgM, IgG2a, and IgG2b. In contrast, Ab isotypes generated by the KLH construct were IgM and IgG1. This suggests that the molecular adjuvant-containing vaccine induced an Ab class switch characteristic of a Th1-like response and, consequently, generated Ab with isotypes distinct from the traditional KLH construct. Thus, the molecular adjuvant appears to induce Ag-specific Abs via an immunologic pathway that differs from the more traditional vaccine design. Finally, mice immunized with the molecular

adjuvant-containing construct displayed no outward signs of immediate or delayed inflammatory responses.

Over the years, we have used epitope-YSFKPMPLaR vaccine constructs to immunize rats, hamsters, rabbits, and cattle to a wide variety of B cell epitopes of various lengths (8 to 35 residues) and chemical modifications such as phospho-Tyr/Ser/Thr-containing epitopes. In all cases, immunizations were performed with the epitope-YSFKPMPLaR construct dissolved merely in unbuffered or phosphate buffered saline (PBS) via simple subcutaneous and/or intraperitoneal injections.

One of the interesting possibilities presented by the molecular adjuvant-containing vaccines is that the molecular adjuvant might enable the processing and presentation of small molecule Ags that are particularly difficult to induce immune response against. In fact, we have generated a molecular adjuvant-containing vaccine to nicotine in which a single nicotine hapten was attached to the N-terminal end of *YKQGGFLGLYSFKPMPLaR* (Nic-*YKQGGFLGLYSFKPMPLaR* (Sanderson et al., 2003). Rats immunized with this construct dissolved only in saline generated nicotine-specific Ab titers and were shown to be resistant to certain nicotine-induced behavioral effects.

46.4.8.2. Generation of Ag-Specific Cell-Mediated Responses

The effectiveness of YSFKPMPLaR to induce a cytotoxic T lymphocyte (CTL) response to a well defined T cell epitope was evaluated by immunizing mice with C5a-active and C5a-inactive constructs in which a T cell epitope from the hepatitis B surface antigen (HBsAg), *IPQSLDSWWTSL*, was attached to the N-terminus and C-terminus of YSFKPMPLaR, respectively (Ulrich et al., 2000). BALB/c mice were immunized with the following constructs: (1) YSF-KPMPLaR; (2) *IPQSLDSWWTSL*; (3) *IPQSLDSWWTSLRR*; (4) the C5a-active constructs *IPQSLDSWWTSLYSFKPMPLaR*, *IPQSLDSWWTSLRRYSFKPMPLaR*, and *IPQSLDSWWTSLRVRRYSFKPMPLaR*; and (5) the C5a-inactive constructs YSFKPMPLaR*RRIPQSLDSWWTSL*, and *IPQSLDSWWTSLRRYSFKPMPLaRG*. Some of these constructs were designed with a protease-sensitive linker sequence between the CTL epitope and the molecular adjuvant in order to provide a cleavage site for intracellular proteases that would separate the CTL epitope from the molecular adjuvant and facilitate its processing and presentation. Two protease-sensitive linker sequences were used in these designs. One was a double-Arg sequence (**RR**), which is sensitive to proteases of the subtilisin family (Barr, 1991) and other trypsin-like proteases. The other was a sequence specific to the ubiquitous intracellular subtilisin-like protease furin (**RVRR**) (Gordon et al., 1995).

BALB/c mice were immunized subcutaneously with 50–100 µg of the above constructs dissolved only in 100 µl of sterile PBS and were boosted at 21-day intervals. Spleen cells were harvested, incubated with 150 nM of the HBsAg CTL

epitope (*IPQSLDSWWTSL*), and used as effector cells against ^{51}Cr -labeled target cells (P815S) that express the HBsAg.

Consistent with the above Ab results, only those mice immunized with the C5a-active constructs generated Ag-specific, CD8^+ CTL responses. Interestingly, of the C5a-active constructs used in these immunizations, only the two containing the protease-sensitive linker sequences induced a CTL response; i.e., *IPQSLDSWWTSLRRYSFKPMPLaR* and *IPQSLDSWWTSLRVRRYSFKPMPLaR*, but not *IPQSLDSWWTSLYSFKPMPLaR*. This observation appears to implicate the importance of an intracellular proteolytic event in separating the epitope from the molecular adjuvant for facilitating Ag/epitope processing and presentation. Finally, mice immunized with either YSFKPMPLaR or the C5a-active epitope-YSFKPMPLaR constructs displayed no outward signs of immediate or delayed inflammatory responses.

In a related study (Pisarev et al., 2005), it was shown that murine dendritic cells pulsed with a C5a-active construct made from a T-cell epitope of the degenerate tandem repeat region of MUC1 (*SAPDNRPAL*) attached to the molecular adjuvant (*SAPDNRPALRRYSFKPMPLaR*) induced epitope-specific type 1 T cells. Also, spleen cells from mice transgenic for human MUC1 on the genetic background of C57BL/6 mice were stimulated with irradiated spleen cell pulsed with *SAPDNRPALRRYSFKPMPLaR*, *SAPDNRPAL*, or a structurally similar epitope *SAPDTRPAP*. Immunization with *SAPDNRPALRRYSFKPMPLaR* induced significant responses to both epitopes, while immunization with *SAPDNRPAL* alone induced responses only to the *SAPDNRPAL* epitope. These results demonstrate the ability of the molecular adjuvant-containing construct, *SAPDNRPALRRYSFKPMPLaR*, to induce significant epitope-specific type 1 T-cell responses to cross-reacting epitopes *SAPDNRPAL* and *SAPDTRPAP* derived from different regions of MUC1.

The immunization results obtained from the YSFKPMPLaR-induced humoral and cell-mediated responses suggest that the molecular adjuvant deliver both Ag and stimulatory signals to C5aR-bearing APCs; events that are consistent with the mechanism shown in Figure 46.1. The YSFKPMPLaR moiety of the epitope-YSFKPMPLaR construct interacts with C5aRs expressed on the surface of APCs, particularly dendritic cells, and induces the synthesis/release of cytokines that provide the "help" necessary to engage/activate helper T and/or B cells necessary for the observed CTL and Ab responses, respectively. Following the molecular adjuvant-mediated release of cytokines, the C5aR-ligand complex internalizes and carries the attached epitope into the APC cytoplasm where it is processed by various intracellular Ag processing pathways. The epitope then associates with MHC class I determinants that are subsequently expressed on the APC surface with the bound epitope (Tempero et al., 1997).

Although this mechanism of action for the molecular adjuvant still needs to be effectively characterized and is a major focus of research in our laboratory, it may suggest a novel pathway of exogenous MHC class I Ag presentation such

FIGURE 46.1. Proposed Mechanism for C5a Agonist Molecular Adjuvant. (1) The molecular adjuvant with an attached antigen binds to C5aRs on the surface of the APC. (2) The molecular adjuvant induces the release of Th1 cytokines. (3) The molecular adjuvant-vaccine/C5aR complex internalizes. (4) The antigen attached to the molecular adjuvant is processed by intracellular Ag processing pathways. (5) The processed Ag binds to intracellular MHC determinants. (6) The Ag is presented on the surface of the APC.

as that described previously using both *in vitro* and *in vivo* systems (Sigal et al., 1999; Raychaudhuri and Rock, 1998). Since it has been generally assumed that class I-mediated Ag presentation involves the generation of epitopes from endogenously synthesized proteins, the finding that extracellular proteins could be taken up by professional APCs (particularly macrophages and dendritic cells), processed in the cytoplasm or perhaps endosomes to yield antigenic epitopes, which are presented in association with MHC class I determinants, is of considerable significance. The molecular adjuvant moiety of these constructs, therefore, appears to both target the attached epitope to C5aR-bearing APCs and enhance the Ag processing/presentation capacity of the APC. Thus, the molecular adjuvant embodies adjuvant properties characteristic of both a vehicle and an immunomodulator.

The expression of an Ag-specific immune response appears to be critically dependent upon the ability of the molecular adjuvant to interact with C5aRs expressed on APCs; however, the extent to which the size of the epitope would sterically interfere with this C5aR/molecular adjuvant interaction is not yet known. All the epitopes we have used to date have been peptides ranging in length from 8 to 35 residues, but it is conceivable that whole proteins could be used as Ags in such molecular adjuvant-containing vaccines. Such a vaccine could be readily generated by attaching a chemically-active or photochemically-active linker to the N-terminal end of YSFKPMPLaR during solid-phase synthesis (Hansen et al., 1996), which then could be used to decorate the surface a

protein with multiple copies of YSFKPMPLaR. Such a vaccine construct would have the obvious advantage of containing an Ag having multiple B- and T- cell epitopes that could cover a range of immunogenic responses. Again, whether the size of the protein Ag would disallow the smaller YSFKPMPLaR to interact with C5aRs on APCs is unknown.

These Ab and CTL responses observed with YSFKPMPLaR *in vivo* support the therapeutic potential of response-selective agonists of C5a as molecular adjuvants. Furthermore, such encouraging results justify the continued design of analogues that exhibit more potent and more selective C5a-like immunostimulatory properties. Our and other laboratories are actively engaged in structure-function studies of such analogues with the goal of identifying new topochemical features that could be introduced into the design of C5a agonists that may express an affinity and selectivity for C5aRs on APCs.

46.4.9. Improved Molecular Adjuvant Design: N-Methylation of Backbone Amides

Our structure-function analyses of YSFKPMPLaR implicated the importance of extended backbone conformation as introduced by the two Pro residues at positions 69 and 71 (Finch et al., 1997; Vogen et al., 1999a,b). However, the substitution of a Pro residue to induce such extended conformation also removes the contribution made the side-chain of the substituted residue. Thus, we generated a panel of YSFKPMPLaR analogues in which methyl groups were introduced onto certain backbone amide nitrogen atoms. The presence of an amide methyl group forces an extended backbone conformation of the preceding residue, R_{n-1} , in a manner similar to Pro (Hruby and Nikiforovich, 1991), but retains the biologic contribution made by the side-chain of the residue now bearing the N-methyl group.

From this panel of N-methylated analogues, one (YSFKDMP(MeL)aR) was shown to be considerably more potent in and selective for eicosanoid release from macrophages than enzyme release from neutrophils relative to YSFKPMPLaR (Vogen et al., 2001). Furthermore, binding of YSFKDMP(MeL)aR to C5aRs on human neutrophils could not be detected, but YSFKDMP(MeL)aR binding to C5aRs on macrophages was comparable with YSFKPMPLaR (Vogen et al., 2001). This *in vitro* response-selectiveness was confirmed *in vitro* by a study the vasopressive and neutropenic effects of natural C5a, YSFKPMPLaR, and YSFKDMP(MeL)aR were evaluated in a rat model (Vogen et al., 2001). Rats were anesthetized and administered 2 μ g/kg hrC5a and 3 μ g/kg YSFKPMPLaR or YSFKDMP(MeL)aR intravenously. YSFKDMP(MeL)aR, identical to YSFKPMPLaR and hrC5a, exhibited a pronounced and rapid decrease in mean blood pressure that recovered to control levels over 90 minutes. However, in marked contrast to YSFKPMPLaR

and hrC5a, YSFKDMP(MeL)aR exhibited no neutropenia or changes in circulating blood volume.

The presence of N-methyl groups on the backbone of the molecular adjuvant YSFKPMPLaR dramatically alters its selectivity for C5aR-mediated activity in macrophages versus neutrophils and may provide a synthetic approach for the development of highly response-selective agonist of C5a and, consequently, molecular adjuvants with little/no inflammatory effects via the engagement of C5aR-bearing neutrophils. Indeed, preliminary results suggest that YSFKDMP(MeL)aR, like YSFKPMPLaR, behaves as an equally effective molecular adjuvant capable of inducing a robust, Ag-specific CTL response to various CTL epitopes (Floreani, A., Heires, A., and Sanderson, S., 2006 unpublished results).

46.5. Advantages of Molecular Adjuvant-Containing Vaccines

Molecular adjuvant-containing vaccines are generated by straightforward, standard, solid phase peptide synthesis, which allows for several advantages over conventional vaccines. Peptide synthesis allows for the elegant control the number of Ags/epitopes attached to the molecular adjuvant. Thus, the exact Ag-to-molecular adjuvant ratio and chemical composition for each lot of vaccine produced can be known, a huge advantage in quality control during manufacture. Peptide synthesis is inexpensive and amenable to scale-up. Thus, hundreds of kilograms of a molecular adjuvant-containing vaccine can be produced in a few days using commercially available equipment. In contrast to conventional vaccines, a molecular adjuvant-containing vaccine is a chemical rather than a biological product. Thus, recombinant methods are not required to generate any vaccine component and, consequently, it can be generated with great purity using standard HPLC methods with no DNA, viral, or bacterial contamination. Vaccine purity and quality can be assured and controlled, therefore, by in-house monitoring. At the end of this purification process, the vaccine is lyophilized to a dry powder, which has a shelf life of years at room temperature. Thus, the vaccine can be readily distributed in this dry powdered form to the clinic where it need only be taken up in saline for the deliverable vaccine formulation when needed. As such, a viable and long shelf-life after distribution can be assured.

Summary

This chapter has highlighted some of the characteristics of traditional and non-traditional adjuvants, the advantages and disadvantages of their use in vaccines, and has introduced the concept of molecular adjuvants as a way to improve immune

outcome while minimizing undesirable side-effects. A particular emphasis was placed on the generation of conformationally-restricted, response-selective agonists of the complement component C5a and their potential as molecular adjuvants and at least one synthetic approach by which their molecular adjuvant properties may be improved. Such molecular adjuvant-containing vaccines appear to have tremendous therapeutic, manufacturing, and commercial potential. However, the development and use of such molecular adjuvants and molecular adjuvant-containing vaccines represent only one approach to producing vaccines capable of meeting the modern-day threats posed by antibiotic-resistant strains of bacteria and bioterrorism. It is clear that a well-organized and concerted worldwide effort that utilizes multiple approaches to novel adjuvant and vaccine designs will be required to overcome these growing threats to human and animal populations.

Review Questions/Problems

1. The majority of adjuvants in experimental use today are composed of various bacterial components. Briefly explain the rationale for the use of such bacterial components in adjuvants.
2. Briefly describe the two major biological functions of the complement system.
3. The complement-derived anaphylatoxin C5a has many prominent immune stimulatory properties and, consequently, is a good candidate for use as a molecular adjuvant. However, its use as such would be severely limited. Describe the major limitation(s) for the use of natural C5a as a molecular adjuvant.
4. Antigen presenting cells (APC) represent an important class of immune cells essential for generating an antigen-specific immune response. Briefly describe the basic cellular mechanism by which APCs contribute to this antigen-specific immune outcome.
5. Conventional vaccines in use today typically require the use of added adjuvants to initiate and potentiate an antigen-specific immune response. In contrast, vaccines that incorporate the conformationally-biased agonists of C5a as molecular adjuvants described in this chapter require no added adjuvants – vaccinations are accomplished with just water/saline as the vehicle. Describe why this is possible.
6. In addition to the ability to target antigens to C5a receptor-bearing APCs, the conformationally-biased C5a agonists/molecular adjuvants induce C5a-like responses at the C5a receptor on the APC. Describe these C5a-like responses.
7. Describe why the conformationally-biased C5a agonists/molecular adjuvants invoke their effects at the C5a receptor expressed on APCs, but not C5a receptors expressed on inflammatory neutrophils.
8. Bacteria and various components of bacteria are used as adjuvants in order to provide the bacterial signals that activate principally
 - a) antibody synthesis
 - b) the innate arm of immunity
 - c) clonal expansion of B cells
 - d) oxidative phosphorylation
9. Adjuvants typically fall into two major categories, which are
 - a) vesicles and nanoparticles
 - b) proteins and DNA
 - c) live and attenuated
 - d) vehicles and immunomodulators
10. The two principal biological effects of complement component C5a are
 - a) intercalation of DNA and *de novo* protein synthesis
 - b) inflammation and immune stimulation
 - c) neo-vascularization and spleen development
 - d) protease activation and carbohydrate clearance
11. The C-terminal region of complement-derived C5a (C5a65-74) represents
 - a) the biologically active region of C5a
 - b) a post-translational signal sequence
 - c) a site for phosphorylation by kinases
 - d) an immunogenic site recognized by T lymphocytes
12. A molecular adjuvant can be defined by all of the following *except*:
 - a) targets antigens to dendritic cells
 - b) is a single molecular entity
 - c) down regulates costimulatory factors
 - d) activates specific pathways of antigen presentation

47.1. Introduction

The blood brain barrier (BBB) is one of the most challenging barriers for drug delivery in the body. It significantly restricts the entry of low molecular weight compounds and biomacromolecules to the brain from the periphery. Inefficient delivery of the drugs, DNA and proteins to the brain is a major bottleneck in development of more efficacious and safe modalities for diagnostics and treatment of neurological diseases, especially at early stages of the disease when the BBB remains intact. The low permeability of the BBB is attributed, in large part, to the brain microvessel endothelial cells (BMVEC), which form tight extracellular junctions and have low pinocytotic activity (Mayhan, 2001; Pardridge, 2005a). Some relatively lipophilic and low molecular weight substances can transport across the BMVEC by passive diffusion. However, a large number of lipophilic compounds are rapidly effluxed from the brain into the blood by extremely effective drug efflux systems expressed in the BBB (Begley, 1996; Fromm, 2000; Tamai and Tsuji, 2000; Loscher and Potschka, 2005a). These efflux systems include P-glycoprotein (Pgp), Multidrug Resistance Proteins (MRPs), breast cancer resistance protein (BCRP), and the multi-specific organic anion transporter (MOAT). There is also an enzymatic barrier to drug transport in the BMVEC. Activity of many enzymes that participate in the metabolism and inactivation of endogenous compounds, such as γ -glutamyl transpeptidase, alkaline phosphatase, and aromatic acid decarboxylase is elevated in cerebral microvessels (Minn et al., 1991; Abbott and Romero, 1996). These features of the BBB require discovery of new modalities allowing for effective drug delivery to the central nervous system (CNS), which is of great need and importance for treatment of neurodegenerative disorders.

A number of earlier publications and extensive reviews on delivery of small drug molecules and biomacromolecules to the brain are available in the literature (Spector, 2000; Lo et al., 2001; Banks and Lebel, 2002; Cornford and Cornford, 2002; Pardridge, 2002a, b; Begley, 2004a; Kas, 2004; Gaillard et al., 2005; Garcia-Garcia et al., 2005; Liu et al., 2005; Liu and Chen, 2005; Loscher and Potschka, 2005b; Pardridge, 2005a; Roney et al., 2005). The present chapter describes recent findings in the development of a new generation of polymer nanomaterials for drug delivery to the CNS.

47.2. History and Principles of Drug Delivery Using Polymers

The original discovery of a polymer drug delivery system was published in 1964 by Folkman and Long (Folkman and Long, 1964). This work reported that hydrophobic low molecular weight drugs can diffuse through the wall of silicone tubing at a controlled rate. Since then, polymers have occupied a central status in controlled drug release as well as in the fabrication of drug delivery systems (Langer, 2001; Duncan, 2003). During the past decades a large number of drug delivery systems, mostly in the form of microspheres, films, tablets, or implantation devices, have been designed to achieve sustained drug release by taking advantage of the unique properties of polymers.

There are several fundamental properties of polymers that are useful in solving drug delivery problems. First, polymers can be designed to be intrinsically multifunctional and can, for example, be combined either covalently or non-covalently with drugs to overcome multiple problems such as solubility, stability, permeability, etc. Second, polymers can be easily modified with various targeting vectors to direct drugs to specific sites in the body. Third, polymers can be designed to be environmentally responsive materials, allowing for the controlled and sustained release of a drug at its site of action. Finally, polymers themselves can

be biologically active, and this property can be exploited in order to modify the activity of various endogenous drug transport systems within the body to improve delivery and, therefore, drug performance.

Numerous polymer-based therapeutics are on the market or undergoing clinical evaluation to treat cancer and other diseases. Many of them are low molecular weight drug molecules or therapeutic proteins that are chemically linked to water-soluble polymers to increase drug solubility, drug stability, or enable site-specific transport of drugs to target tissues affected by the disease.

Recently, as a result of the rapid development of novel nanotechnology-derived materials, a new generation of polymer therapeutics has emerged which uses materials and devices of nanoscale size for the delivery of drugs, genes, and imaging molecules (Kabanov et al., 1995a; Salem et al., 2003; Savic et al., 2003; Kabanov and Batrakova, 2004; Missirlis et al., 2005; Nayak and Lyon, 2005; Trentin et al., 2005). These materials include liposomes, dendrimers, polymer micelles, polymer-DNA complexes ("polyplexes"), and other nanostructured materials for medical use, that are collectively called nanomedicines. Compared to the first generation of polymer therapeutics, the new generation of nanomedicines is more advanced. They entrap small drugs or biopharmaceutical agents, such as therapeutic proteins and DNA, and can be designed to trigger the release of these agents at the target site. Moreover, they can be targeted not only to the particular organ or tissue, but to a particular cell or even an intracellular compartment. The essence of nanotechnology is the ability to work at the molecular level to create large structures with fundamentally new molecular organization. Materials with features on the scale of nanometers often have properties different from their macroscale counterparts. Many nanomedicines are constructed using self-assembly principles, such as spontaneous formation of micelles or interpolyelectrolyte complexes driven by diverse molecular interactions (hydrophobic, electrostatic, etc.). Nanotechnology focuses not only on formulating therapeutic agents in biocompatible nanocomposites but also on exploiting distinct advantages associated with a reduced dimensional scale within 1–100 nm. Some examples of nanoscaled polymeric carriers involve polymer conjugates, polymeric micelles, and polymersomes (Panyam and Labhasetwar, 2003). Because these systems often exhibit similarity in their size and structure to natural carriers such as viruses and serum lipoproteins, they offer multifaceted specific properties in drug delivery applications (Lavasanifar et al., 2002). There is still a lack of understanding in terms of why certain arrangements of small molecules cause dramatic changes in their behavior. With this in mind, the goal of this chapter is to explore current research in polymeric nanoparticles, where the specific arrangement of the polymeric matter at the nanoscale imparts new properties that are not attainable from simple polymer solutions, and to summarize their applications for drug delivery systems to the CNS.

47.3. Nanocarriers for Drug Delivery

The need for a protective drug carrier for CNS drugs is highlighted by the fact that many drugs have a low hydrolytic stability and are subject to degradation by blood proteins or by enzymes encountered in the BBB. Furthermore, a drug carrier can be targeted via receptor-mediated transport using a brain-specific vector moiety. A single unit of a given drug carrier can incorporate many drug molecules, resulting in high "payloads" per one targeting moiety. By increasing the payload of the carrier, one might improve the efficacy of the delivery while maintaining a relatively low level of involvement of numbers of targeted moieties and receptors. There are various types of vehicles proposed for transport of neuropharmaceuticals across the BBB: liposomes, degradable nanoparticles, nanospheres, nanosuspensions, polymeric micelles, nanogels, block ionomer complexes, nanofibers and nanotubes (Figure 47.1).

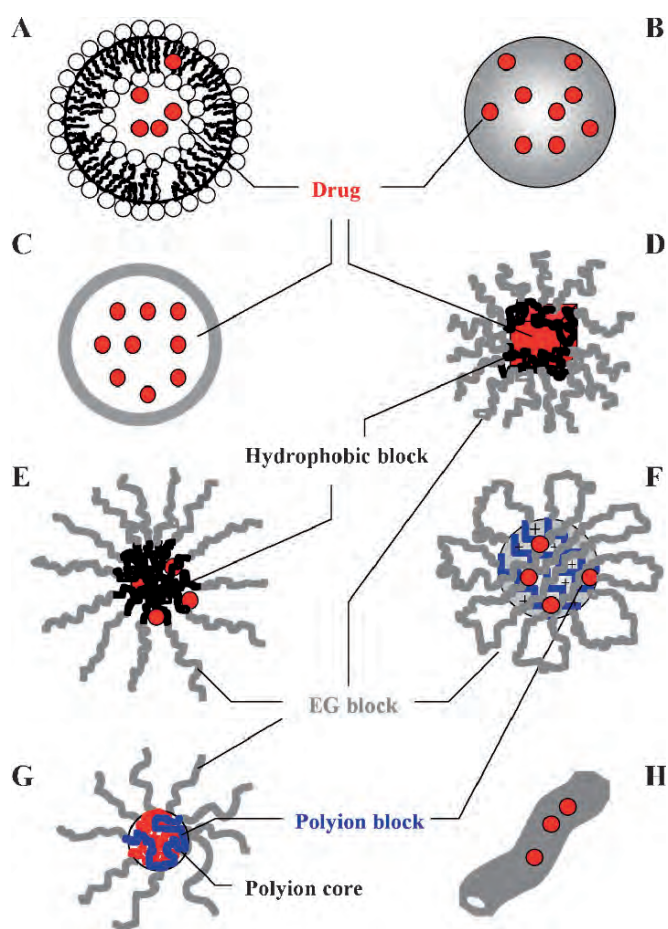

FIGURE 47.1. Types of nanocarriers for drug delivery. A: liposomes; B: nanoparticles; C: nanospheres; D: nanosuspensions; E: polymer micelles; F: nanogel; G: block ionomer complexes; H: nanofibers and nanotubes.

47.3.1. Types of Nanocarriers for Drug Delivery to the Brain

Liposomes are vesicular structures, which are usually composed of unilamellar or multilamellar lipid bilayers (similar to biological membranes) that surround internal aqueous compartments (Figure 47.1A). The size of the vesicles varies from several nanometers to several microns. Relatively large amounts of drug molecules can be incorporated into either the aqueous compartment (water soluble compounds) or the lipid bilayers (lipophilic compounds) providing the possibility to use liposomes as carriers for drug delivery. The use of liposomes for drug delivery across the brain capillaries has been reported extensively (Umezawa and Eto, 1988; Huwyler et al., 1996; Rousseau et al., 1999; Shi et al., 2001; Mora et al., 2002; Thole et al., 2002; Wu et al., 2002; Omori et al., 2003; Schmidt et al., 2003; Zhang et al., 2003b; Aoki et al., 2004; Gosk et al., 2004; Chekhonin et al., 2005; Pardridge, 2005b). In general, encapsulation of a drug into liposomes prolongs the circulation time of the drug in the blood stream, reduces adverse side effects, and in selected cases enhances therapeutic effects of CNS agents. Conventional liposomes containing hydrocortisone were demonstrated to penetrate the BBB in experimental autoimmune encephalomyelitis (Rousseau et al., 1999). In addition, liposomes prepared using lecithin, cholesterol, and *p*-aminophenyl- α -mannoside were efficiently transported across the BBB into mouse via mannose receptor-mediated transcytosis (Umezawa and Eto, 1988). An interesting approach using thermosensitive liposomes loaded with an antineoplastic agent, doxorubicin (Dox), for treatment of malignant gliomas was reported (Aoki et al., 2004). These liposomes released their content when the tumor core was heated to 40°C by a brain heating system. Elevated accumulation of the drug in the brain of the heated animals resulted in a significantly longer overall survival time compared to the non-heated animals.

Conventional liposomes normally are cleared rapidly from the circulation by the reticuloendothelial system. Extended circulation time of these carriers can be accomplished with small-sized liposomes (<100nm) composed of neutral, saturated phospholipids and cholesterol. Further, it was demonstrated that water-soluble polymers such as polyethylene glycol (PEG) attached to the surface of liposomes reduce adhesion of opsonic plasma proteins, and decrease recognition and rapid removal of liposomes from the circulation by the mononuclear phagocyte system in liver and spleen (Huwyler et al., 1996; Kozubek et al., 2000; Voinea and Simionescu, 2002). Using this approach, PEG-coated ("PEGylated") long-circulating liposomes (or "stealth liposomes") were shown to remain in the circulation with a half-life as long as 50h in humans (Gabizon et al., 1994). Particularly, commercial PEGylated liposome-encapsulated Dox, Doxil, was already approved for use in the treatment of recurrent ovarian cancer and AIDS-related Kaposi's sarcoma (Gabizon et al., 2003) and was shown to be effective in patients with metastatic breast cancer (Papaldo et al., 2006). Long-circulating PEGylated liposomes were also used for the delivery of high

doses of glucocorticosteroids to the CNS to treat multiple sclerosis (Schmidt et al., 2003). The PEGylated liposomes encapsulating prednisolone provided selective targeting to the inflamed CNS in rats (up to 4.5-fold higher accumulation compared to the healthy animals). The mechanism of preferential accumulation of these liposomes in the brain is not fully understood. It appears to be crucial that the liposomes exhibit long-circulating behavior. Their effect is related to either (1) the change in the pharmacokinetics of the encapsulated drug resulting in a greater drug exposure to the BBB or (2) to liposome capture by monocytes/macrophages (in liver, spleen, or blood) followed by cell-mediated transport to the brain.

Attachment of targeting moieties to PEGylated liposomes can direct them to the BBB. Thus, efficient delivery of PEG-liposomes conjugated with transferrin (Tf) to the post-ischemic cerebral endothelium was achieved in rats (Omori et al., 2003). The expression of Tf receptor in the cerebral endothelium was reported to increase with a peak at the first day after induced transient middle cerebral occlusion, which can be employed for drug delivery to the brain after stroke. PEGylated immunoliposomes were also successfully employed to target and transfect brain tissues (Shi et al., 2001). A plasmid DNA was encapsulated within the liposome. Packaging of the DNA in the interior of the liposome prevented degradation of the therapeutic gene by the ubiquitous endonucleases *in vivo*. These liposomes were directed to Tf receptor-rich tissues, such as brain, liver, and spleen by monoclonal antibodies, OX26, that were linked to the free termini of the PEG chains. When a reporter gene was also coupled with a brain-specific glialfibrillary acidic protein promoter, its expression was achieved predominantly in the brain (Shi and Pardridge, 2000).

In addition considerable work was reported on antibodies to transferrin receptor, OX26, that were linked to the surface of PEGylated liposomes via PEG spacers. Such immunoliposome constructs were used to deliver small drugs, Daunomycin (Huwyler et al., 1996), and Digoxin (Huwyler et al., 2002) as well as plasmid DNA (Shi et al., 2001) to the brain. Notably, OX26-conjugated liposomes selectively distributed to BMVEC but avoided choroid plexus epithelium, neurons, and glia (Gosk et al., 2004). In related work OX26 antibodies directly linked to oligonucleotides (Wu et al., 1996) or fibroblast growth factor (Wu et al., 2002) enhanced delivery of these molecules to the brain.

Another example of a brain targeting vector with a remarkable species-specificity is reported by Coloma et al. (Coloma et al., 2000). This vector was genetically engineered from monoclonal antibody to the human insulin receptor, 83-14Mab, where most of the immunogenic murine sequences were replaced by a human antibody sequence. The intravenously administered antibody showed robust transport to the brain in a rhesus monkey but not in a rat. Furthermore, this vector was also used for targeting liposomes with reporter genes to the brain (Zhang et al., 2003b). As a result, the level of gene expression in the brain was 50-fold higher in the rhesus monkey as compared to the rat.

Monoclonal antibody directed insulin or Tf receptors were also utilized to target PEGylated immunoliposomes for transvascular

gene therapy of Parkinson's disease (PD) (Pardridge, 2005b). In the 6-hydroxydopamine rat model of experimental PD, striatal tyrosine hydroxylase (TH) activity was completely normalized after an intravenous administration of Tf α Ab-targeted liposomes carrying a TH expression plasmid. Treatment of PD using this approach may be possible with dual gene therapy that seeks both to replace striatal TH gene expression with TH gene therapy, and to halt or reverse neurodegeneration of the nigro-striatal tract with neurotrophin gene therapy.

The mechanism by which immunoliposomes penetrate across the BBB is not fully understood. It was hypothesized that the process involves the binding of immunoliposomes to multiple capillary luminal membrane receptors, fusion of the liposomes with several vesicular pits into a large vesicle and transcytosis of this vesicle to the abluminal membrane border (Cornford and Cornford, 2002). Studies by electron microscopy support this hypothesis (Faustmann and Dermietzel, 1985).

In addition to approaches pursuing delivery across the intact BBB, the methods are developed to target sites in the brain under conditions when the integrity of the BBB is compromised by the progressing disease. For example, PEGylated immunoliposomes were coupled with the monoclonal anti-GFAP antibodies (Chekhonin et al., 2005). Experiments with cell cultures demonstrated specific and competitive binding of these immunoliposomes to embryonic rat brain astrocytes. Administered intravenously into rats, the immunoliposomes displayed typical kinetics with elimination half-lives of 8–15 h. Being incapable of penetrating the unimpaired BBB, these immunoliposomes, can be used to deliver drugs to glial brain tumors that express GFAP or to other pathological loci in the brain with a partially disintegrated BBB (Chekhonin et al., 2005).

Another approach involving temporal opening of the BBB using liposomes was proposed by Zhang et al. (Zhang et al., 2004). An endogenetic bioactive peptide, RMP-7 ("cereport") that is known to open tight junctions in the BBB by affecting bradykinin 2 receptors, was linked to conventional liposomes. It was demonstrated that transport of vectorized liposomes loaded with HRP was increased three times in an *in vitro* model of the BBB compared to the non-vectorized vehicles (Zhang et al., 2004). However, potential toxicological implications of such approach still need to be addressed.

Overall, liposomes have been extensively studied for CNS drug delivery showing increased drug efficacy and reduced drug toxicity. While the examples presented suggest that the liposome technology provides a promising approach for CNS drug delivery, a considerable limitation of liposomes is their relatively low loading capacity for water-insoluble drugs and biomacromolecules.

Nanoparticles are solid species of nanoscale size usually composed of an insoluble and biodegradable polymer or polymer blend (Figure 47.1B). Generally, the methods of preparation of such nanoparticles are simple and easy to scale-up. The drug is captured within the particle upon its preparation and is released upon degradation of the polymer in the body. The use of nanoparticles as carriers for drug and gene delivery has been

an area of intensive research and development for over a decade (Moghimi et al., 1990; Gref et al., 1994; Peracchia et al., 1998; Torchilin, 1998; Vinogradov et al., 1999; Lemieux et al., 2000; Alyaudtin et al., 2001; Calvo et al., 2002; Gupta et al., 2003; Moghimi and Szebeni, 2003; Kreuter, 2004; Vinogradov et al., 2004; Cui et al., 2005; Liu et al., 2005; Roney et al., 2005). The surface of such carriers is often modified by a PEG brush to increase the stability of nanoparticles in dispersion and extend circulation time of nanoparticles in the body (Peracchia et al., 1998; Torchilin, 1998; Calvo et al., 2002). To allow for efficient transcytosis across the BMVEC the particle size must be kept small and not exceed ca. 100–200 nm.

For example, poly(butyl)cyanoacrylate nanoparticles were successfully used to deliver a wide range of drugs to the CNS, which were either incorporated into the particle structure or absorbed onto the particle surface (Alyaudtin et al., 2001; Calvo et al., 2001; Calvo et al., 2002; Kreuter et al., 2003; Kreuter, 2004; Steiniger et al., 2004). Prior to administration in the body, the nanoparticles were coated with a PEG-containing surfactant, Tween 80. After the administration, they also absorbed apolipoprotein E available in the blood. The resulting coated nanoparticles were transported across the cerebral endothelial cells by endocytosis via the low density lipoprotein (LDL) receptor. They localized in the ependymal cells of the choroid plexuses, the epithelial cells of the ventricles, and, to a lower extent, in the capillary endothelial cells. The list of the drugs delivered to the CNS in these constructs include, analgesics (dalargin, loperamide), anti-cancer agents (Dox), anticonvulsants (NMDA receptor antagonist, MRZ 2/576), and peptides (dalargin and kytorphin) (Kreuter et al., 2003; Steiniger et al., 2004). Particularly, incorporation of MRZ 2/576, into such nanoparticles prolonged the anticonvulsive activity of the drug almost twofold compared to the drug alone (Frieze et al., 2000). Dox bound to the nanoparticles was successfully used for treatment of an aggressive human cancer, glioblastoma, resulting in increased survival times in rats (Steiniger et al., 2004). Enhanced transport of Dox in the nanoparticles to the brain involved bypassing the P-glycoprotein (Pgp) and MRP efflux systems in the BBB that impede the delivery of the drug alone. In another example the nanoparticles were coupled with chelators (desferioxamine or D-penicillamine) and proposed for treatment of Alzheimer disease (AD) and other CNS diseases by reducing oxidative stress in the brain (Liu et al., 2005; Cui et al., 2005). However, a concern regarding the toxicity associated with this delivery approach has somewhat hampered further development for specific therapeutic applications (Olivier et al., 1999). The methods for preparation of nanoparticles commonly employ the use of organic solvents that may result in degradation of immobilized drug agents, especially biomacromolecules.

Nanospheres are hollow nanosized particles (Figure 47.1C) that can be prepared by microemulsion polymerization or covering the surfaces of colloidal templates with thin layers of the desired material followed by selective removal of the templates (Hyuk Im et al., 2005). The carboxylated polystyrene nanospheres (20 nm) were evaluated for drug delivery

to CNS (Yang et al., 2004). It was demonstrated that these carriers accumulated in the brain *in vivo* following cerebral ischemia and reperfusion. The intravenously injected nanospheres remained in the vasculature under normal conditions. However, during cerebral ischemia-induced stress that leads to the opening of tight junctions between endothelial cells the extravasation of the nanospheres to the disease site was increased (Kreuter, 2001). Therefore, polystyrene nanospheres may have potential clinical applications for CNS delivery of drugs and imaging agents during ischemia and stroke.

Nanosuspensions of hydrophobic drugs have also attracted attention as drug delivery systems (Rabinow, 2004). These systems represent crystalline particles of a solid drug, which are often stabilized by nonionic PEG-containing surfactants (Figure 47.1D) (Jacobs et al., 2000). They can be manufactured by a variety of techniques such as media milling, high-pressure homogenization or by employing emulsions and microemulsions as templates (Friedrich and Muller-Goymann, 2003; Friedrich et al., 2005). The major advantages of the nanosuspension technology includes its simplicity and general applicability to most drugs including very hydrophobic compounds (Muller et al., 2001; Friedrich et al., 2005). It was suggested that similar to regular nanoparticles (described above), the surface modification of nanosuspensions with Tween 80 may increase the delivery of these particles to the brain (Muller et al., 2001). Currently nanosuspensions of anti-retroviral drugs are evaluated in animal models for CNS delivery and treatment of HIV infection in the brain using cell-mediated delivery approach described below (H. Gendelman, University of Nebraska Medical Center).

Polymeric micelles represent core-shell structures that spontaneously form in aqueous solutions of amphiphilic block copolymers (Figure 47.1E). Block copolymers are polymers containing at least two chains of different chemical nature, for example, a hydrophilic and a hydrophobic chain. In aqueous solutions above a threshold concentration, called a “critical micelle concentration” (CMC) the individual block copolymer molecules termed “unimers” form micelles composed from dozen to a couple of hundred of molecules. The size of the micelles usually varies in the range of from 10 to 100 nm. The hydrophobic chains of the block copolymers segregate forming a hydrophobic core of the micelles while the hydrophilic chains (often PEG) form a hydrophilic protective shell. Polymer micelles can incorporate considerable amounts (up to 20–30% wt.) of hydrophobic compounds. The resulting nanomaterials can serve as carriers for drug delivery (“*micellar nanocontainers*”) (Kataoka et al., 2001; Kwon, 2003; Allen and Cullis, 2004; Torchilin, 2004; Moghimi and Agrawal, 2005; Torchilin, 2005; Aliabadi and Lavasanifar, 2006; Tao and Uhrich, 2006). The core-shell architecture of polymeric micelles is essential for their pharmaceutical application. The core is a water-incompatible compartment that is hidden from the aqueous exterior by the hydrophilic chains of the corona, preventing premature drug release and degradation. The hydrophilic shell maintains the micelles in a dispersed state and decreases undesirable drug interactions with cells and

proteins through steric-stabilization effects. Upon reaching the target the incorporated drug is released from the micelle via diffusion mechanisms. Polymeric micelles have been extensively evaluated in multiple pharmaceutical applications as drug delivery systems (Kabanov et al., 1989c; Kabanov et al., 2002; Jones et al., 2003; Torchilin et al., 2003; Aliabadi et al., 2005; Bronich et al., 2005; Gaucher et al., 2005; Lee et al., 2005; Miyata et al., 2005; Uchino et al., 2005; Yan and Tsujii, 2005), and carriers for diagnostic imaging agents (Torchilin, 2002). Several clinical trials have been completed or are underway to evaluate polymer micelles for the delivery of anti-cancer drugs for chemotherapy of tumors (Danson et al., 2004; Valle et al., 2004); (Nishiyama et al., 2003). Polymeric micelles formed by Pluronic, PEG-phospholipid conjugates, PEG-b-polyesters, or PEG-b-poly(L-amino acid)s were proposed for drug delivery of poorly water-soluble compounds, such as amphotericin B, propofol, paclitaxel, and photosensitizers (Lavasanifar et al., 2002; Kwon, 2003; Adams and Kwon, 2004; Vakil and Kwon, 2005). It was also emphasized that using polymeric micelles one can significantly increase the drug transport into the brain.

One of the early studies of targeted drug delivery to the brain used micelles of Pluronic block copolymers as carriers for CNS drugs (Kabanov et al., 1989c; Kabanov et al., 1992a). These micelles were conjugated with either polyclonal antibodies against brain α_2 -glycoprotein or insulin to target the receptors at the luminal side of BMVEC. Both the antibody-conjugated and insulin-conjugated micelles were shown to effectively deliver a drug or a fluorescent probe incorporated into the micelles to the brain tissue *in vivo* (Kabanov et al., 1992a). Studies that monitored animal behavior as a means to determine the pharmacological activity of dopamenergic compounds, such as mobility and grooming were performed. It was demonstrated that incorporation of a neuroleptic, haloperidol, into the Pluronic micelles vectorized with insulin resulted in 25-fold enhancement of the neuroleptic effects compared with the free drug. Vectorization of the drug-loaded micelles with antibodies lead to an even more pronounced (up to 500-fold) enhancement of the neuroleptic effects. Subsequent studies demonstrated that the insulin vectorized micelles undergo receptor-mediated transcytosis in BMVEC from luminal (blood) to abluminal (brain) side (Batrakova et al., 1998).

A new type of functional polymer micelles with cross-linked ionic cores was recently developed (Bronich et al., 2005). Instead of using amphiphilic block copolymers these micelles are prepared using double hydrophilic block copolymers with nonionic (PEG) and ionic blocks. The micelles are self-assembled by reacting the ionic block with a condensing agent of an opposite charge. The ionic chains incorporated into the core of the micelles were chemically cross-linked and then the condensing agent was removed. The resulting cross-linked micelles contain a hydrophilic ionic core, which is swollen in water, and a hydrophilic PEO shell. The core can incorporate various hydrophilic drugs and imaging agents, which can be then delivered to the target

site in the body. Overall, this strategy has potential for the development of novel modalities for delivery of various drugs to the brain, including selected anti-cancer agents to treat metastatic brain tumors as well as HIV protease inhibitors to eradicate HIV virus in the CNS.

Nanogels are a new family of hydrophilic carriers that were recently developed for targeted delivery of biomacromolecules and other drug molecules to the brain (Vinogradov et al., 1999; Vinogradov et al., 2004; Vinogradov et al., 2005a; Vinogradov et al., 2005b). Nanogels represents a nanoscale size polymer network of cross-linked ionic, e.g. polyethyleneimine (PEI), and nonionic PEG chains (Figure 47.1F). It swells in an aqueous solution and collapses upon binding of a drug through ionic interactions. Because of the effect of PEG chains, the collapsed nanogel forms stable dispersions with the particles size of ca. 80 nm. Nanogels can spontaneously absorb biomacromolecules including oligonucleotides (ODNs), plasmid DNA and proteins as well as small charged molecules. A key advantage is that the nanogels display very high loading capacities, 40–60% “payload” by weight, which is not achieved with conventional nanocarrier systems. The transport of ODNs incorporated in the nanogel particles across an *in vitro* model of the BBB was recently reported (Vinogradov et al., 2004). To enhance delivery across the BBB the surface of the nanogels were modified by either Tf or insulin (Vinogradov et al., 2004). Both peptides were shown to increase transcellular permeability of the nanogel and enhance delivery of ODNs across BMVEC monolayers. Overall, the nanogels were shown to be a promising carrier for CNS drug delivery, although only in the early stages of development. *Block ionomer complexes* are formed as a result of the reaction of double hydrophilic block copolymers containing ionic and nonionic blocks with biomacromolecules of opposite charge including oligonucleotides, plasmid DNA and proteins (Figure 47.1G) (Kabanov et al., 1995b; Harada and Kataoka, 1999a, b; Nguyen et al., 2000; Harada and Kataoka, 2003; Zhang et al., 2003a; Jaturanpinyo et al., 2004). For example, block ionomer complexes were prepared by reacting trypsin or lysozyme (that are positively charged under physiological conditions) with an anionic block copolymer, PEG-poly(R, α -aspartic acid) (Harada and Kataoka, 1999a; Jaturanpinyo et al., 2004). Such complexes spontaneously assemble into nano-sized particles having a core-shell architecture. The core contains polyion complexes of the biomacromolecules and ionic block of the copolymer. The shell is formed by the nonionic block. These nanomaterials were shown to efficiently deliver DNA molecules *in vitro* and *in vivo* into a cell and release them at the site of action (Roy et al., 1999; Nguyen et al., 2000; Harada-Shiba et al., 2002; Junghans et al., 2005). To improve stability of the complexes in the body the biopolymer and block ionomer can be additionally cross-linked with each other (Harada and Kataoka, 2003; Jaturanpinyo et al., 2004) or the polyion chains of the block ionomer within the core can be cross-linked using degradable links. The advantages of such systems in drug delivery applications include simplicity and versatility of the design allowing the incorporation of consid-

erable amounts of different biomacromolecules. Furthermore, block ionomer complexes are environmentally responsive nanomaterials allowing for biomacromolecule release in response to an external stimulus such as change of pH (acidification), concentration and chemical structure of elementary salt, etc.

Nanofibers and nanotubes (Figure 47.1H) have considerable promise in futuristic biomedical applications, for example, for sustained drug release from implants, or as channels for tiny volumes of chemicals in nanofluidic reactor devices, or as the “world’s smallest hypodermic needles” for injecting molecules one at a time. These nanomaterials have a prototype in nature. In an organism, microtubules and their assembled structures are critical components for a broad range of cellular functions—from providing tracks for the transport of cargo to forming the spindle structure in cell division. There are various types of synthetic nanofibers and nanotubes manufactured from carbon, silicon, or diverse natural or man-made polymers. They can be vapor-grown (Che et al., 1998), self-assembled from peptide amphiphiles (Bull et al., 2005; Guler et al., 2005) or electrospun manufactured from virtually any polymer material (Dzenis, 2004). Carbon nanotubes and nanofibers have lately attracted great attention in nanomedicine including their potential use as drug carriers, although there are also considerable concerns associated with their safety (Lange et al., 2003; Muller et al., 2005). Self-assembled nanofibers can be designed to incorporate diverse chemical functionalities and thus may have a variety of applications for delivery of small drugs, biomacromolecules or imaging contrast agents (Bull et al., 2005; Guler et al., 2005). Electrospun continuous nanofibers are unique since they represent nanostructures in two dimensions and a macroscopic structures in another dimension (Fong et al., 1999; Dzenis, 2004). They are safer to manufacture than the carbon nanotubes since there is less risk of air pollution.

At present a few studies of nanofibers and nanotubes are focused on CNS drug delivery. One study evaluated electrospun nanofibers of a degradable polymer, PLGA, loaded with anti-inflammatory agent, dexamethasone, for neural prosthetic applications (Abidian and Martin, 2005). A conducting polymer, poly(3,4-ethylenedioxythiophene), was deposited to the nanofiber surface and the coated nanofibers were then mounted on the microfabricated neural microelectrodes, which were implanted into brain. The drug was released by electrical stimulation that induced a local dilation of the coat and increased permeability.

In the future, nanotubes and nanofibers can be administered systemically, if the problem of their toxicity is addressed, for example, by appropriate polymer coating. In this respect, the continuous nanofibers are more likely to be used in implants or tissue engineering applications.

47.3.2. Cell-Mediated Delivery of Nanocarriers to the Brain

A distinct case of the vehicle-mediated CNS drug delivery employs specific cells carriers that can incorporate micro- and

nano-containers (such as liposomes) loaded with drugs and act as perfect Trojan horses by migrating across the BBB and carrying drugs to the site of action (Daleke et al., 1990; Fujiwara et al., 1996; Jain et al., 2003; Khan et al., 2005). It is documented that many neurological diseases, such as Parkinson's disease (PD), AD, Prion disease, meningitis, encephalitis and HIV-associated dementia, have in common an inflammatory component (Perry et al., 1995). The process of inflammation is characterized by extensive leukocytes (neutrophils and monocytes) recruitment. These cells have a unique property of migrating toward the site of inflammation via the processes known as diapedesis and chemotaxis (Kuby, 1994). Their combat arsenal consists of uptake of the foreign particle, producing toxic compounds, and liberation of substances stored in intracellular vesicles via exocytosis. Therefore, these cells can be used for cell-mediated CNS drug delivery when loaded with a drug and administered into the blood stream.

It has been shown that cells capable of phagocytosis, such as macrophages or monocytes/neutrophils, can endocytose colloidal nanomaterials, for example, liposomes, and subsequently release them into the external media (Daleke et al., 1990; Jain et al., 2003). To accelerate the transport of monocytes/neutrophils to the brain site, the drug-containing liposomes were additionally loaded with magnetic particles (Jain et al., 2003). Magnetic liposomes demonstrated about a tenfold increase in brain levels compared to non-magnetic liposomes when local magnetic field was applied. It is noteworthy that both cell types showed preferential uptake of liposomes containing negatively-charged lipids (such as phosphatidylserine), or liposomes modified with polyanion than liposomes containing only neutral lipids (such as phosphatidylcholine) (Fujiwara et al., 1996). This suggests that by engineering the surface of the nanomaterials one may modulate their uptake into and release from the cell carriers to optimize the therapeutic regimen. The phosphatidylserine-containing negatively charged liposomes were shown to increase therapeutic activity of an encapsulated antifungal agent, chloroquine, against *C. neoformans* infection in the mouse brain (Khan et al., 2005). The chloroquine-loaded liposomes accumulated inside macrophage phagolysosomes and resulted in a remarkable reduction in fungal load in the brain even at low doses compared to the free drug at high doses, thus increasing the antifungal activity of macrophages.

T lymphocytes were also proposed as a potential therapeutic drug carriers for cancer treatment (Steinfeld et al., 2006). The kinetics of loading and release of nanoparticles coated with cytotoxic antibiotic Dox into the cells were examined. It was suggested that the immune cells can accomplish target-specific and sheltered transport to the diseased site.

Ability of host cells to home diseased sites after *ex vivo* manipulation is a fundamental requirement and a major problem for their use as vehicles to target locally acting gene therapy to specific diseased sites. It was demonstrated that in the short term, up to 2h after re-implantation, macrophages accumulate primarily in the lungs and, to a lesser extent, in the liver and spleen rather than in the target diseased tissue. A small proportion of

manipulated macrophages (ranging from 0.2 to 28.8%) homes to the diseased site of interest following systemic administration. However, the presence of labeled macrophages in these sites was found to persist for at least 6–7 days in both of these mouse studies (Audran et al., 1995). Therefore, increasing the amount of cell carriers reaching the target site appears to be a crucial point in this type of drug delivery system.

47.3.3. Permeability Enhancers for CNS Drug Delivery

There are a number of efflux mechanisms within the CNS that influence drug concentrations in the brain. Some of them are passive while others are active. Recently much attention has been focused on the so-called multi-drug efflux transporters: Pgp, MRP1, and BCRP, MOAT that belong to the ABC cassette (ATP-binding cassette) family (Pardridge, 1998; Tamai and Tsuji, 2000; Begley, 2004b). Cerebral capillary endothelium expresses a number of efflux transport proteins, which actively remove a broad range of drug molecules before they cross into the brain parenchyma. Pgp is the most thoroughly investigated brain efflux transport protein with broad affinity for dissimilar lipophilic and amphiphilic substrates (Tsuji and Tamai, 1997). As a consequence, the therapeutic value of many promising drugs, such as protease inhibitors for HIV-1 encephalitis (ritonavir, nelfinavir, and indinavir) (Kim et al., 1998), anti-inflammatory drugs (prednisolone, dexamethasone and indomethacin) for treatment of microglial inflammation during idiopathic PD and AD (Tsuji and Tamai, 1997; Perloff et al., 2004), neuroleptic agents (amitriptyline and haloperidol) (Uhr et al., 2000), analgesic drugs (morphine, beta-endorphin, and asimadoline) (Moriki et al., 2004), as well as anti-fungal agents (itraconazole and ketoconazole) (Miyama et al., 1998), is diminished, and cerebral diseases have proven to be most refractory to therapeutic interventions. Moreover, delivery of many anticancer agents (Dox, vinblastine, taxol, etc.) to the brain for treatment of brain tumors (Tsuji, 1998), and drugs for treatment of epilepsy (carbamazepine, phenobarbital, phenytoin, and lamotrigine) (Potschka et al., 2002) is also restricted by the Pgp drug efflux transporter.

An emerging strategy for enhanced BBB penetration of drugs is co-administration of competitive or noncompetitive inhibitors of the efflux transporter together with the desired CNS drug. First generation low molecular weight Pgp inhibitors (cyclosporine A, verapamil, PSC833, etc.) are substrates of the drug efflux transporter, which compete for the active site with the therapeutic agent (Kemper et al., 2003). Second generation inhibitors (LY335979, XR9576 and GF120918) are non-competitive inhibitors, which allosterically bind to Pgp, inactivating it and increasing drug transport to the brain (Kemper et al., 2004). Despite their high efficiency in cell culture models, the small therapeutic range of these inhibitors, high *in vivo* toxicity, and fast clearance are the main obstacles for their therapeutic application.

Recently, a new class of inhibitors (nonionic polymer surfactants) was identified as a promising component of drug

formulations. These compounds are two- or three-block copolymers arranged in a linear AB or ABA structure. The A block is a hydrophilic PEG chain. The B block can be a hydrophobic lipid (BRIJs, MYRJs, Tritons, Tweens, and Chremophor), or a poly(propylene glycol) (PPG) chain (Pluronics) (Figure 47.2).

Studies in multidrug resistant (MDR) cancer cells, polarized intestinal epithelial cells, Caco-2, and polarized BMVEC monolayers provided compelling evidence that selected Pluronic block copolymers can inhibit drug efflux transport systems (Miller et al., 1997; Batrakova et al., 1998; Batrakova et al., 1999a; Batrakova et al., 2001a; Batrakova et al., 2001b; Batrakova et al., 2003b). Specifically, in primary cultured BMVEC monolayers, used as an *in vitro* model of BBB, the inhibition of drug efflux systems, Pgp and MRP was associated with an increased accumulation and permeability of a broad spectrum of drugs in the BBB, including low molecular drugs (Batrakova et al., 1998; Miller et al., 1999) and peptides (Witt et al., 2002). These effects were most apparent at concentrations below the CMC (Miller et al., 1997; Batrakova et al., 1998). It was suggested that the unimers, are responsible for the inhibition of Pgp and MRPs efflux transport system. Incorporation of the probe into the micelles formed at high concentrations of the block copolymer decreases its availability to the cells and reduces the transport of this probe in BMVEC.

Recent findings suggest that effects of Pluronic on drug efflux transport proteins involve interactions of the block copolymers with the cell membranes (Batrakova et al., 2001b; Batrakova et al., 2003b). It was demonstrated that a fine balance is needed between hydrophilic (PEG) and lipophilic (PPG) components in the Pluronic molecule to enable inhibition of the drug efflux systems (Batrakova et al., 2003a). Overall, the most efficacious block copolymers are those with intermediate lengths of PPG block and relatively hydrophobic structure (HLB < 20), such as Pluronic P85 or L61 (Batrakova et al., 1999b). The hydrophobic PPG chains of Pluronic immerse into the membrane hydrophobic areas, resulting in alterations of the membrane structure and

decreases in its microviscosity ("membrane fluidization"). Pluronic at relatively low concentrations (e.g. 0.01%) inhibits the Pgp ATPase activity, possibly due to conformational changes in the transport protein induced by the immersed copolymer chains in the Pgp-expressing membranes (Batrakova et al., 2001b). In particular, Pluronic P85 displayed the effects characteristic of a mixed type enzyme inhibitor—decreasing maximal reaction rate (V_{\max}) and increasing Michaelis constant (K_m) for ATP as well as Pgp-specific substrates such as vinblastine (Batrakova et al., 2004a). The magnitude of these effects for vinblastine was as high as over 200-fold V_{\max}/K_m change (interestingly, MRP1 ATPase activity was affected less, which could explain somewhat smaller effects of Pluronic on this transporter). In contrast, at high concentrations (e.g. 1%), binding of Pluronic to the membrane actually resulted in restoration of Pgp ATPase activity. This could be due to the segregation of the block copolymer molecules in the 2D clusters in the membrane, which diminishes its interactions with the transport proteins.

Various drug resistance mechanisms, including drug transport and detoxification systems, require consumption of energy to sustain their function in the barrier cells. Because of this fact, mechanistic studies have focused on the effects of Pluronic block copolymers on metabolism and energy conservation in BMVEC (Batrakova et al., 2001a). The basis for such studies was the earlier reports that Pluronic block copolymers can affect mitochondria function and energy conservation in the cells (Kirillova et al., 1993). Recent studies have demonstrated that exposure to Pluronic P85 induced significant decrease in ATP levels in BMVEC monolayers (Batrakova et al., 2001b). The observed energy depletion was due to inhibition of the cellular metabolism rather than a loss of ATP in the environment. The study of Rapoport et al. suggested that Pluronic P85 can be transported into the cells and decrease the activity of electron transport chains in the mitochondria (Rapoport et al., 2000). Remarkably, the ATP depletion induced by Pluronic appears to be tightly linked to the specific cell phenotype, since this effect is observed selectively in the cells that overexpress Pgp (as well as MRPs) (Batrakova et al., 2001b; Kabanov et al., 2003b; Kabanov et al., 2003a; Batrakova et al., 2004a). We suggested that inhibition of ATP production in high energy-consuming cells, such as cells overexpressing Pgp, results in the rapid exhaustion of intracellular ATP, i.e. ATP depletion (Batrakova et al., 2001b). Further, our recent studies indicate that these differences were related to the differences in the major fuel sources used by MDR or sensitive cells (fatty acids vs. glucose respectively) (Rapoport et al., 2006). It was shown that Pluronics affected the stage of the electron entrance in the mitochondrial electron transport chain, presumably due to the interaction of the hydrophobic block of the copolymer with fatty acids, which decreased fuel transport into the mitochondria matrix. In contrast, Pluronics exerted only mild effect on the glucose-based respiration in drug-sensitive cells. Overall, the energy depletion (decreasing ATP pool available for drug transport proteins) and membrane interactions (inhibiting of ATPase activity of drug transport proteins) are critical factors collectively contributing

FIGURE 47.2. Pluronic block copolymers with various numbers of hydrophilic EO (n) and hydrophobic PO (m) units are characterized by distinct hydrophilic-lipophilic balance (HLB). Due to their amphiphilic character these copolymers display surfactant properties including ability to interact with hydrophobic surfaces and biological membranes. In aqueous solutions at concentrations above critical micelle concentration (CMC) these copolymers self-assemble into micelles.

FIGURE 47.3. Schematic illustrating twofold effects of Pluronic block copolymers with intermediate lipophilicity on Pgp and MRPs drug efflux system. These effects include (a) decrease in membrane viscosity ("fluidization") resulting in inhibition of Pgp and MRPs ATPase activity, and (b) ATP depletion in BMVEC. Extremely lipophilic or hydrophilic Pluronic block copolymers do not cross the cellular membranes and do not cause energy depletion in the cells.

to a potent inhibition of the drug efflux systems by Pluronic (Batrakova et al., 2001b) (Figure 47.3).

The effect of Pluronic P85 on drug transport to the brain was evaluated in animal experiments (Batrakova et al., 2001a). Brain delivery of a Pgp substrate, digoxin, administered intravenously in the wild-type mice expressing functional Pgp, was greatly enhanced in the presence of Pluronic P85. It was found that the digoxin brain/plasma ratios in the Pluronic treated animals were practically the same as those in the knockout mice, an animal model that is deficient in both *mdr1a* and *mdr1b* isoforms of Pgp. This suggests that co-administration of Pluronic with the drug in mice resulted in inhibition of Pgp in the BBB of the wild-type animals (Batrakova et al., 2001a).

One possible concern in these studies is that by virtue of inhibiting the ATP in BMVEC, the copolymer may display toxic effects on the BBB. However, the ATP depletion was found to be transient; following removal of the block copolymers from BMVEC monolayers the initial ATP levels were restored (Batrakova et al., 2001b). Although there were significant decreases in cellular ATP following Pluronic treatment, even during peak depletion of ATP by Pluronic there was no evidence of loss of barrier functions of BBB as demonstrated using ^3H -mannitol as a permeability marker both *in vitro* and *in vivo* (Batrakova et al., 1998; Batrakova et al., 2001a). Moreover, Pluronic does not affect the glucose transporter, GLUT1, and only slightly inhibits the lactate transporter, MCT1, the two

transporters playing an important role in the brain metabolism (Batrakova et al., 2004b). Pluronic also does not inhibit the amino acid transporters, LAT1, CAT1, and SAT1, in the BBB (Zhang et al., 2006). A histochemical examination of the tissue sections obtained from animals treated with Pluronic revealed no pathological changes in the BBB. Importantly, no cerebral toxicity of any kind has been observed in the human Phase I and Phase II studies of SP1049C, a Pluronic-based formulation of Dox to treat MDR tumors (Danson et al., 2004; Valle et al., 2004). It is possible, that this formulation, evaluated in human trials, can be adopted for use with CNS drugs to enhance drug delivery to the brain.

47.3.4. Chemical Modification of Polypeptides with Fatty Acids and Amphiphilic Block Copolymers

Delivery of potentially therapeutic polypeptides and proteins to the brain is significantly hampered by the BBB. The hydrophilicity, the lack of stability due to enzymatic or chemical degradation, and the lack of transport carriers capable of shuttling polypeptides across cell membranes all play a part in precluding most polypeptides from transport into the brain (Lee, 1991). Several approaches to modify polypeptides to alter their BBB permeability have been attempted. First, conjugation of proteins with wheatgerm agglutinin (Raub and Audus, 1990; Banks and Broadwell, 1994) or cationic groups ("cationization") (Kumagai et al., 1987; Triguero et al., 1989; Triguero et al., 1991) was shown to enhance delivery of polypeptides to the brain through adsorptive endocytosis. The cationized polypeptides demonstrated enhanced permeability and greater accumulation in the brain *in vitro* and *in vivo*. However, toxicity and antigenicity of cationized polypeptides could be an issue for their medical use (Bickel et al., 2001). Further, vectors targeting polypeptides to insulin and Tf receptors (monoclonal antibodies) have been considered to enhance passage of these compounds to the brain through receptor-mediated endocytosis (Frank et al., 1986; Duffy and Pardridge, 1987; Friden et al., 1991; Bickel et al., 2001). Thus, potential therapeutic polypeptides, basic fibroblast growth factor and brain-derived neurotrophic factor, were conjugated to OX26, which resulted in increased entry of these polypeptides to the brain and increased drug neuroprotective effects (Zhang and Pardridge, 2001a, 2001b; Song et al., 2002).

Another approach, artificial hydrophobization of polypeptides with a small number of fatty acid residues (e.g. stearate or palmitate) has been shown to enhance cellular uptake (Kabanov et al., 1989a). Specifically, this technique involves point modification of lysine or N-terminal amino groups with one or two fatty acid residues per protein molecule. As a result of such modification, the protein molecule remains water-soluble but also acquires hydrophobic anchors that can target even very hydrophilic proteins to cell surfaces (Slepnev et al., 1995). To obtain low and controlled degrees of modification, a system of reverse micelles of a surfactant, sodium bis-(2-ethylhexyl)sulfosuccinate (Aerosol OT) in octane was used as a reaction medium (Kabanov et al., 1987) (Figure 47.4). Over a

FIGURE 47.4. Chemical modification of the protein with a water-insoluble reagent in the reverse micelles of Aerosol OT in octane. (1) Protein molecule incorporates into the inner water pool of the reverse micelle, acquiring a monolayer cover of the hydrated surfactant molecules. (2) The modifying reagent incorporates into the surfactant layer of the micelle coming into contact with the modified group of the protein. (3) Following the completion of the reaction the modified protein is precipitated and the surfactant and excess of the reagent are removed by adding cold acetone. Proteins modified with fatty acid residues with controlled and low degree of modification are obtained.

dozen water-soluble polypeptides (enzymes, antibodies, toxins, cytokines) have been modified by this method (Kabanov et al., 1987; Kabanov et al., 1989b; Alakhov et al., 1990; Chekhonin et al., 1991; Robert et al., 1993; Robert et al., 1995; Slepnev et al., 1995). Further studies of interactions of the fatty acylated polypeptides with cells were also conducted (Hashimoto et al., 1989; Kabanov et al., 1989b; Alakhov et al., 1990; Col-sky and Peacock, 1991; Melik-Nubarov et al., 1993; Ekrami et al., 1995; Slepnev et al., 1995; Chopineau et al., 1998; Kozlova et al., 1999). Modification of water-soluble polypeptides, such as HRP, resulted in enhanced polypeptide binding with the cell membranes and internalization in many cell types (Slepnev et al., 1995). The point modification does not inhibit the specific activity of the polypeptides in the cells. To the contrary, in selected cases, when polypeptides are known to exhibit their effects in cells through binding with a cell surface receptor (e.g. *Staphylococcus aureus* enterotoxin A and recombinant α -interferon) the modification resulted in significant (10 to 100 times) enhancement of these effects (Alakhov et al., 1990; Kabanov et al., 1992b). The increased activity of selected modified polypeptides in cells can possibly be explained by their concentration at the cell membrane, which promotes their binding with receptors (Kabanov et al., 1992b). Furthermore, insulin modified with one palmitic acid residue produced a prolonged hypoglycemic effect compared to the native insulin after intravenous injection and was shown to be less immunoreactive than the native insulin (Hashimoto et al., 1989).

The relevance of this technology to CNS delivery emerged from the studies by Chekhonin et al. (Chekhonin et al., 1991; Chekhonin et al., 1995). Those studies showed that modification of the Fab fragments of antibodies against gliofibrillar acid protein (GFAP) and brain specific alpha 2-glycoprotein (alpha 2GP) with stearate led to an increased accumulation of the modified Fab fragments in the brain in a rat. Furthermore,

a neuroleptic drug conjugated with the stearylated antibody Fab fragments was much more potent compared to the free drug. In comparison, fatty acylated Fab fragments of non-specific antibodies did not accumulate in the brain but instead accumulated in the liver, while stearylated Fab fragments of brain-specific antibodies displayed preferential accumulation in the brain (Chekhonin et al., 1991). The mechanism by which the stearylated Fab-fragments were directed to the brain was not elucidated at that time. It was not clear also whether the Fab fragments actually crossed the BBB or remained associated with the luminal surface of the brain capillaries. Subsequent studies using bovine brain microvessel endothelial cells (BBMEC) as an *in vitro* model of BBB (Chopineau et al., 1998) demonstrated that stearylolation of ribonuclease A (approx. 13.6 kDa) increases the passage of this enzyme across the BBB by almost tenfold. Of the three fatty acid derivatives analyzed—myristic, palmitic and stearic, the latter was the most active. A possible mechanism for the entry of the fatty acylated polypeptides to the brain is adsorptive endocytosis. Given the characteristics of the BBB transport for nonessential free fatty acids as reviewed elsewhere (Banks et al., 1997), it is unlikely that the modified polypeptides are able to use those transporters. Thus, use of free fatty acid receptor mediated transport by the modified polypeptides is not likely. However, if such a pathway is feasible, it should be more pronounced when the essential fatty acids, such as linoleic, are used to modify polypeptides (Edmond et al., 1998; Edmond, 2001).

A similar principle was used in the case of a protein modification with Pluronic block copolymers (Figure 47.5); the designed conjugates had different balance between hydrophilic and lipophilic properties (Batrakova et al., 2005). The cell binding and transport of Pluronic P85 and L121 modified HRP were increased up to six and ten times, respectively, compared with the native HRP. A method of conjugation using biodegradable and non-biodegradable links was also varied. As expected, the modification of the protein via a biodegradable link (Figure 47.5A) resulted in the most effective transport of the protein across the brain microvessel endothelial cell monolayers. It is likely, that being highly hydrophilic the HRP molecule requires a highly lipophilic moiety to obtain the optimal hydrophilic-lipophilic balance of the conjugate. Such a lipophilic group has a tendency to remain associated with the cellular membrane as an anchor. Therefore, a biodegradable link allowed the polypeptide molecule to separate from its lipophilic moiety and enter the brain after the conjugate passed membranes of the barrier cells. Data obtained by confocal microscopy visualizes this effect. Modification of the protein with Pluronic P85 via biodegradable link drastically enhanced the transport of HRP into the cells and its accumulation in the cytoplasm, nuclei, and other cellular organelles (Figure 47.5B). It was suggested that the protein conjugate was initially bound to the cellular membrane through the Pluronic moiety incorporated into the lipid bilayer followed by cleavage of the HRP molecule from the Pluronic anchors. *In vivo* studies demonstrated that

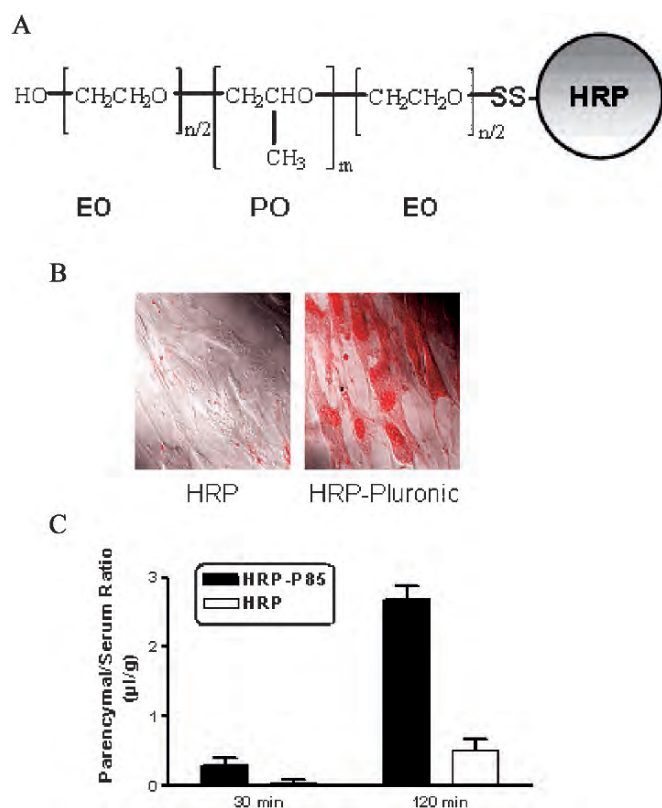

FIGURE 47.5. Effect of HRP modification with Pluronic block copolymer on transport across the BBB in an in vitro and in vivo models. A: HRP conjugated with Pluronic P85 via the biodegradable bond; B: confocal microphotograph of BBMEC monolayers treated with rhodamine-labeled HRP and Pluronic-HRP for 2 h; C: blood-to-brain transport of HRP and Pluronic-HRP in mice.

1) hydrophobization with stearyl group or 2) amphiphilic modification with a Pluronic block copolymer had increased the rate of HRP penetration across the BBB and increased accumulation of HRP by the brain (Figure 47.5C). Overall modification with Pluronic block copolymers appeared to be more promising for HPR delivery to the brain. In this case the permeability of modified protein in the BBB *in vivo* was increased almost fourfold with no statistically significant effects on the protein peripheral pharmacokinetics or entry into the parenchymal space.

Summary

Tremendous efforts in the last several decades have resulted in numerous inventions of CNS drug delivery systems. Many of these innovative systems have a significant potential for the development of new biomedical applications. The wide variety of strategies reflects the inherent difficulty in transport of therapeutic and imaging agents across the BBB. In fact, the

effective combination of several approaches, such as encapsulation of drugs into nanoparticles conjugated with vector moieties or using micelles of Pluronic block copolymers along with Pluronic “unimers” that will inhibit drug efflux transporters in the BMVEC, may give the most promising therapeutic outcomes.

Review Questions/Problems

1. What are the main features of the BBB that restrict drug transport to the brain?
2. Describe the properties of polymers that are useful for drug delivery systems.
3. What are the advantages of nanoscaled polymeric carriers?
4. List types of nanocarriers for drug delivery. Describe their structure, principal differences, advantages and limitations.
5. Describe cell-mediated drug delivery to the CNS.
6. Explain how the drug efflux transporters affect drug transport to the brain? List examples of drug efflux transporters expressed in the BBB.
7. Describe three generations of inhibitors of drug efflux transporters in the BBB.
8. Describe the effects of Pluronic block copolymers on drug efflux transporters in the BBB.
9. How is the chemical modification of polypeptides with fatty acids and amphiphilic block copolymers applied to increase delivery of polypeptides to CNS?
10. Which of the following molecules can penetrate across the BBB through passive diffusion?
 - a. Lipophilic low molecular weight compounds
 - b. Hydrophilic low molecular weight compounds
 - c. Lipophilic high molecular weight compounds
 - d. Hydrophilic high molecular weight compounds
11. What size of polymer nanocarriers is the most appropriate for drug delivery?
 - a. 0.1–1 nm
 - b. 1–100 nm
 - c. 100–1,000 nm
 - d. 1–100 µm
12. Which types of drugs can be incorporated into polymeric micelles?
 - a. lipophilic compounds
 - b. hydrophilic compounds
 - c. charged compounds
 - d. proteins compounds

13. What does CMC mean?

- a. colloidal microemulsion complex
- b. cell monocarrier
- c. critical micelle concentration
- d. contrast multi-compound

14. Which polymer is used to stabilize nanoparticles in an aqueous dispersion?

- a. polystyrene
- b. polymethacrylic acid
- c. DNA
- d. PEG
- e. polycyanoacrylate

15. Which type of cells can be used for cell-mediated delivery?

- a. brain microvessel endothelial cells
- b. neurons
- c. macrophages
- d. astrocytes
- e. erythrocytes

48.1. Introduction

Central nervous system (CNS) diseases represent a class of complex disorders for which cures have been largely unmet due to the general lack of knowledge regarding underlying pathogenic mechanisms. Gene-based therapies directed at ameliorating neurodegenerative diseases exhibit great potential due to rapid scientific advances made regarding delivery modalities, neurosurgical methods, neuroimaging, and molecular biological manipulation. Given these breakthroughs, the diseased CNS presents a neuroimmunological challenge as gene delivery many times requires invasive surgical procedures and a majority of the gene delivery platforms incite transient, and sometimes, inflammatory events that possess the potential to exacerbate disease-related processes. In this chapter, we will discuss the most current literature on gene therapy for CNS disorders by detailing the neuroimmunological profiles of presently available gene transfer platforms, approaches that have been made to minimize vector-mediated inflammation, and ways in which the immune system can be harnessed to prevent and/or treat neurodegenerative diseases via gene-based immunotherapy.

48.2. Vector Selection Rationale

To derive an informed decision in the selection of an appropriate gene therapeutic vehicle for the treatment of a specific neurologic disease, the following must be considered: vector capacity, tropism, genome maintenance, vector-mediated transgene expression duration and levels, and safety profile.

The size of the therapeutic transcription unit is many times employed as an initial criterion to focus vector choice. This category also includes a given vector's ability to harbor multiple transcription units, thereby potentially affording reconstitution of a complex biochemical pathway (i.e., dopamine biosynthesis for Parkinson's disease). Potential applications for several presently available vector platforms are restricted by insert size limitations and are sometimes excluded if multi-gene delivery is a prerequisite for therapy.

Cell type specificity is also an important issue when developing a gene-based therapeutic intervention for neurodegenerative disorders. It would be most beneficial if the vector of choice could transduce and express in cell types that comprise only the specific disease-affected pathway. Vector tropism can be regulated through modulation of cellular receptor interactions by one or more of the following approaches: alteration of virus docking proteins, utilization of alternate viral serotypes, pseudotyping, and introduction of tethered ligands for cellular receptors into the viral envelope. Once a vector is optimally targeted to the brain region of interest, therapeutic transgene expression can be restricted to selected cell populations via the utilization of cell type-specific promoters and/or transcriptional elements (Wagner et al., 1992; Zatloukal et al., 1992; Beer et al., 1998; Toyoda et al., 1998; Zabner et al., 1999). Strict spatial control of transgene expression is vital to ensure the correct cells will manufacture the gene product. This control, in turn, reduces the risk that ectopic transgene expression will occur and lead to untoward effects on adjacent neurological pathways.

Most neurodegenerative disorders evolve insidiously over many years thus requiring gene-base modalities to impart therapeutic benefit for several decades of an individual's lifetime. To this end, a vector genome should be stably maintained within the transduced cell for extended periods of time. Vector genome maintenance is, therefore, a critical factor in selection of an appropriate gene therapy vehicle for neurodegenerative diseases. Vector genomes can exist as episomes and/or integrated forms within nuclei of host cells. Mitotically active cells, such as those of the progenitor and glial lineages, eventually exhibit diminished

episomal vector-mediated transgene expression. However, the post-mitotic property of CNS neuronal populations does not exclude the utilization of episomal vectors since genomes can be maintained without progressive therapeutic vector loss due to mitosis. Integrating vectors circumvent this issue but their use raises safety concerns including their potential to transactivate proximal proto-oncogenes and to disrupt essential host genes via insertional mutagenesis.

Another similar issue regarding vector selection relates to the desired levels and duration of gene product expression for treatment of neurodegenerative disorders. Depending upon the vector and transcriptional elements chosen, pharmacologic or physiologic levels of transgene expression can be achieved for time periods of short or long duration. As with other selection criteria, the decision of which level/duration of expression is preferred rests heavily on what aspect of the particular disorder is to be targeted and at which time during the disease course the intervention is to be implemented. Early interventions may require maintenance of long-term physiologic levels of transgene expression (i.e., neuroprotective strategies) since the neural networks may be primarily intact at this time. A vector/promoter combination that safely and stably maintains gene expression at nearly physiologic levels in the CNS would serve as a potential candidate for such early treatment approaches. Treatment modalities that are implemented after presentation of clinical symptoms may require long-term pharmacologic levels of transgene product to restore function to a brain region decimated by disease.

Safety is of utmost concern regarding the application of novel gene therapeutic strategies within the brain. Many presently available vectors trigger immunogenic and/or inflammatory responses when introduced into the CNS. These responses are known to arise from the humoral and/or cell-mediated arms of the immune system, and the magnitude differs depending upon which vector type is employed. For example, repeat administration of early generation viral vectors has been shown to lead to lower transgene expression and serious inflammation, likely the result of a primed immune system (Byrnes et al., 1996). Therefore, a vector that is stably maintained and that can express its transgene for extended periods of time would be a more favorable choice as a gene therapeutic vehicle for neurodegenerative conditions. Another aspect that is often overlooked regarding gene therapy safety is the role of transgene products in the elaboration of immune responses and toxicity. Transgene products that are of foreign origin, ectopically expressed, or pharmacologically expressed harbor the potential to induce cytotoxicity and/or immune responses. Research addressing these issues is imperative to elucidate the role of transgene products in the elaboration of these potentially harmful responses, and how such responses can be successfully circumvented. Utilization of regulatable transcriptional or post-transcriptional elements in delivery vectors to provide "fine-tuning" of therapeutic transgene expression levels is a way to minimize harmful clinical outcomes.

48.3. Gene Transfer Platforms

Genetic material can be delivered to cells by two broad classes of vectors: nonviral and viral. Nonviral gene transfer modalities include the use of plasmid DNA directly or in an encapsulated state. Such approaches are deemed the safest due to the lack of inflammatory and/or immunogenic components, but require repeated administration to maintain therapeutic gene expression. Viral vectors exploit the evolutionary achievements of viruses to propagate, package and transfer genetic material from cell to cell and organism to organism. Via genetic modification of mammalian viruses, it is possible to specifically target gene expression in desired cellular populations. Adenovirus, AAV, lentivirus, and HSV-based vectors as they have been utilized for CNS-directed gene therapy will be discussed below. These vector types represent a subset of the more commonly used viral vectors for CNS gene delivery.

48.3.1. Nonviral Gene Transfer

Although viral gene delivery systems have proven more efficient for use in the nervous system, viral vector production requires special expertise and equipment, and remains time and labor intensive. As an alternative to viral vectors, transfection techniques utilizing cationic lipids have shown promise for use with cells of the nervous system and may prove to exact fewer adverse effects. Conventional nonviral systems (reviewed in Anwer et al., 2000), which rely on passive cell targeting through charge interactions, possess several practical advantages over viral delivery of transgenes. These include decreased production time and costs as well as greater safety, since there is no risk of viral vector recombination.

For more than a decade, there have been a variety of reports demonstrating the use of lipid reagents for transfection of cells comprising the nervous system with very modest transfection efficiencies, even after optimization (Holt et al., 1990; Loeffler et al., 1990; Jiao et al., 1992; Matter-Sadzinski et al., 1992; Kaech et al., 1996). However, more recently our laboratory showed dramatically improved transfection efficiencies in the mouse CNS using the cationic lipids Tfx-10 and Tfx-20 (Promega) to deliver DNA with a microprocessor-controlled injector, suggesting further work towards optimization of lipid transfection is warranted for gene transfer applications requiring direct intracranial administration of therapeutic DNA-lipid complexes (Brooks et al., 1998).

Less invasive methods of delivering nonviral vectors to the CNS would be more desirable. Despite the minimal inflammatory profile of intracranial delivery of DNA-lipid complexes, the potential exists for surgery-induced adverse events, while the relatively limited volume of distribution obtained from stereotactic infusion makes the approach rather infeasible when attempting to treat diseases that involve expansive regions of the brain. To that end, methodologies have been developed to enable the injection of modified

DNA-lipid complexes into the bloodstream that are designed to hone to the brain, and sub-regions thereof, to more widely deliver their therapeutic payload. Nonviral gene delivery systems in particular lend themselves to targeting strategies aimed at achieving higher transfer efficiency and tissue specificity, since they can withstand a wider range of chemical and physical conditions used to incorporate targeting moieties. They also allow for more flexibility and ease-of-use when mixing targeting ligands with plasmid DNA and the lipid delivery reagents.

To approach systemic infusion of targeted DNA-encapsulated liposomes, the liposome formulation requires further modification. Whereas in the case of direct stereotactic injections, cationic liposome-DNA complexes can be used, such complexes highly aggregate in physiological saline leading to inefficient and variable dissemination of the transfection complex when delivered via the bloodstream (Mahato et al., 1997; Matsui et al., 1997). The use of neutral (uncharged) liposomal mixtures in combination with inert and biocompatible polymer polyethylene glycol (PEG) produces sterically stabilized liposomal structures (Papahadjopoulos et al., 1991). Inclusion of PEG is also believed to prevent the binding of opsonins circulating within the bloodstream, thereby significantly decreasing phagocytic cell recognition and clearance (Moghimi and Patel, 1992). Physical targeting of these “pegylated liposomes” through the use of ligands and antibodies has been employed to enhance the efficiency of gene transfer to many specific cell types (reviewed in Anwer et al., 2000), including the CNS (Pardridge, 2003).

The blood-brain barrier (BBB) has long-served as a major obstacle to liposome-based gene delivery to the CNS via systemic administration. Zhang and colleagues have employed a pegylated immunoliposome-mediated method for systemic administration of plasmids expressing tyrosine hydroxylase (TH) in a rodent 6-OHDA model of Parkinson's disease [PD; (Zhang et al., 2004)]. A plasmid construct expressing TH, the rate-limiting enzyme in the dopamine biosynthetic pathway, was encapsulated within pegylated immunoliposomes and injected systemically into parkinsonian rats. High-level transgene expression within the striatum and transient correction of apomorphine-induced rotation behavior were observed, indicating that these nonviral gene transfer reagents were capable of traversing the BBB. In addition, a time-course experiment showed that TH enzyme activity within the striatum diminished substantially from Day 3 to 9 post-treatment. In a recent follow-up study, this group demonstrated that transient gene expression profiles derived from immunoliposome-targeted gene delivery appear to be the result of plasmid degradation *in vivo* (Chu et al., 2006). Immune responses generated against pegylated immunoliposomes are thought to be minimal *in vivo*, but if multiple injections are required to subvert disease progression, then the adaptive immune response may play a role in clearing and/or degrading this gene-based therapeutic.

48.3.2. Adenovirus Vectors

Adenoviruses (Ad) are a family of non-enveloped, double-stranded DNA viruses that generally cause mild respiratory infections in mammals. Over 50 serotypes have been identified. Adenovirus-based vectors are attractive candidates for gene delivery to the CNS, as high vector titers can be generated, and these episomally maintained vectors can efficiently infect and express transgenes in a variety of cell types including the non-dividing cells of the CNS (Akli et al., 1993; Bajocchi et al., 1993; Davidson et al., 1993; Le Gal La Salle et al., 1993; Smith et al., 1996a,b,c). First generation vectors consisted of constructs that lacked genes for the potent regulatory proteins E1A, E1B, and E3. Although high titers could be obtained (approximately 10^{13} viable particles per ml) the immunological and physiological complications that resulted from Ad vector transduction in the CNS were serious. This robust response was due to enhanced cytotoxic T lymphocyte (CTL) activity to viral proteins and/or the expressed transgene product (Tripathy et al., 1996; Michou et al., 1997). Vigorous inflammation precludes repeated administration of this vector. As a consequence of these findings, second generation vectors were developed that additionally lacked the E2A gene. The resultant inflammatory response elicited by these vectors was reduced but still fairly substantial. In an effort to completely remove viral genes from the system, helper virus-dependent or so-called “gutless” forms of Ad vectors were developed (Mitani et al., 1995; Parks et al., 1996; Hardy et al., 1997; Morsy et al., 1998). These forms possess a large transgene capacity (up to 28 kb) and do not express any viral proteins. High multiplicities of infection (MOIs) have been used to infect greater than 85% of neurons with little if any cytotoxicity or adverse physiological effects up to 7 days post-infection (Cregan et al., 2000). Gutless Ad vectors direct expression of therapeutic genes *in vivo* with moderately high efficiency among gene therapy vectors. Gutless Ad constructs, but not first-generation Ad vectors, mediate sustained transgene expression in the brain even in the presence of anti-Ad immunity (Thomas et al., 2000, 2001). Another study, conducted by Zou and colleagues, compared transgene expression from first-generation Ad vectors to gutless Ad vectors in brain. Two months following transduction, the helper-dependent vectors exhibited higher transgene expression and elicited lower numbers of brain-infiltrating macrophages and T cells than first generation Ad vectors (Zou et al., 2000), further speaking to the improved safety profile of this Ad vector iteration.

48.3.3. Adeno-Associated Virus Vectors

Adeno-associated virus (AAV) is a non-pathogenic member of the parvovirus family. Its single-stranded DNA viral genome requires co-infection with either adenovirus or HSV for its own replication/propagation. Wild-type AAV encodes two viral gene products, Rep and Cap, which function in replication/integration and structural stability, respectively. Vectors

derived from AAV can carry up to a 4.5-kb transgene that is flanked by inverted terminal repeats (ITRs). The relatively small payload capacity can be overcome by the co-injection of multiple vectors, each transducing a different therapeutic gene, and leading to co-expression of two linked biochemical functions (Shen et al., 2000). The ITR sequences promote extrachromosomal replication and Rep-mediated genomic integration of the flanked transgene. Newer methods of packaging have led to titers approaching 10^9 transducing units/10 cm plate and have eliminated the need for helper Ad which assures that negligible levels of contaminating Ad helper virus are present in the preparation (Xiao et al., 1998). Once packaged, the unique Cap protein of AAV allows for high-degree virion purification. Helper virus-free AAV vectors elicit transient and minimal inflammatory reactions when delivered *in vivo*, an observation likely due to the lack of associated viral gene expression and the facility to highly purify vector stocks (Kaplitt and Makimura, 1997; Xiao et al., 1997; Bueler, 1999; Lo et al., 1999).

The existence of numerous characterized AAV serotypes allows for use of alternative capsid types in the event serotype-specific neutralizing antibodies are generated or extant, thus extending the utility of the vector platform in the setting of pre-existing AAV immunity. Moreover, each serotype exhibits distinct patterns of transduction within the major tissues of mammals (reviewed by Wu et al., 2006). In general, AAV1 and 5 exhibit higher transduction efficiencies than vectors packaged with serotype 2 capsid in all regions assessed within the CNS (Alisky et al., 2000; Burger et al., 2004), while AAV4 transduces specific cell types, such as ependyma and astrocytes in the subventricular zone, with higher efficiency (Davidson et al., 2000). The varying serotypes not only dictate transduction efficiency, but they have been shown to modulate transgene expression kinetics. The underlying mechanism(s) is unknown, but may be due to differences in virion uncoating and intracellular trafficking within the transduced cell (Thomas et al., 2004).

AAV vectors when delivered into the CNS are capable of expressing transgene products for periods of time in excess of 4 years. This has been demonstrated in both rodent and non-human primate studies [(Kaplitt et al., 1994; McCown et al., 1996; Guy et al., 1999; Lo et al., 1999; Bjorklund et al., 2000; Chirmule et al., 2000; During et al., 2001) and K. Bankiewicz, personal communication]. The pattern and duration of gene expression in these studies suggests that the AAV vectors once introduced into host cells adopt a transcriptional configuration that supports stable expression. This characteristic could lie in the physical status of the AAV vector genome (integrated vs. episomal) following transduction of a given host cell. The ability of wild-type AAV to specifically integrate into human chromosome 19 is intriguing if this property could be translated to AAV-derived vectors (Kotin et al., 1990). The ability to integrate creates the potential for stable, long-term expression of a transgene for the treatment of neurological disorders. Wu and colleagues presented a method for detecting

integrated AAV vector genomes and provided some evidence that integration into CNS cells occurs, however, the specificity of this integration site is yet undetermined (Wu et al., 1998). More recent data generated by the laboratory of Mark Kay suggest that concatenated, non-integrated AAV genomes exist in greater abundance than integrating forms (Chen et al., 2001). To this end, more thorough studies detailing the genome status of AAV vectors *in vivo* must be conducted.

The risk of integration-induced oncogenesis appears to still be a theoretical concern despite a recent report. In long-term rodent studies with rAAV vectors there was a significant increase in the incidence of hepatocellular carcinoma in mice treated with an AAV vector (Daly et al., 2001; Donsante et al., 2001). Systematic investigation was conducted to establish the genesis of the AAV vector/tumor association. These studies employing sensitive quantitative PCR failed to yield evidence that the tumors arose from an insertional mutagenesis event. In a separate study, mice were injected with varying doses of AAV vectors with no evidence of hepatic tumors. These data argue that the hepatic malignancies likely arose by administration of contaminants with the AAV vector stocks and not because of genomic perturbations induced by the vector. However, more recent data compel reexamination of the propensity of rAAV to produce chromosomal alterations. In that study, which was entirely performed in cultured human HeLa cells, AAV vector proviral integrates were found associated with chromosomal deletions and rearrangements most frequently on chromosome 19, nearby but not precisely at the site of wild-type AAV integration (Miller et al., 2002). Multiple explanations for this finding are unexplored and thus its significance is unclear. Assuming safe integration of AAV vectors is demonstrated, a major limitation that will likely persist is the limited transgene size capacity exhibited by these vectors. This shortcoming will prove troublesome when cell-specific promoters and/or transcriptional enhancer elements must accompany the desired therapeutic gene for the purposes of directed expression. One group has attempted to circumvent this issue by developing heterodimeric AAV vectors where transfer of a transcription unit of approximately 9 kb can be achieved (Sun et al., 2000).

48.3.4. Lentivirus Vectors

Replication-defective lentiviral vectors derived from HIV (rHIV) are another promising gene transfer vehicle for CNS applications as they can transduce both dividing and non-dividing cells, do not encode viral proteins, have an approximate 9-kb insert capacity, and are capable of sustaining stable gene expression for greater than a year (Kordower et al., 1999, 2000; Wang et al., 2000; Reilly, 2001). To ensure against the generation of replication-competent HIV virions, the packaging system has been divided into four plasmids and four accessory HIV genes have been deleted from those packaging-assisting plasmids. Titers with this approach yield stocks of $1\text{--}5 \times 10^9$ infectious units (Naldini et al., 1996b; Bensadoun et al., 2000).

HIV-based lentiviral vectors when pseudotyped with the VSV-G protein are principally neurotropic (Desmaris et al., 2001). Entry, proviral derivation and expression appear to occur efficiently in non-dividing neurons without the requirement for disruption of the nuclear envelope (Naldini et al., 1996a,b). Whereas, lentiviral vectors integrate chromosomally in dividing cells, the status of the proviral genome in neurons is less well studied. However, recent evidence garnered from the creation of feline immunodeficiency virus (FIV)-derived vectors devoid of integrase activity suggests that in non-dividing cells, transgene expression levels are equivalent to vectors capable of integrating into the host cell chromosome (Saenz et al., 2004). Efforts to test whether lentiviral vector proviral genomes can be rescued by HIV infection have also been informative. If the vectors retain necessary packaging sequences they are inefficiently rescued (Evans and Garcia, 2000; Follenzi et al., 2000). However, self-inactivating or SIN vectors, which possess major deletions within the U3 and U5 regions of the long terminal repeat (LTR) regions of the lentiviral genome, are unable to be rescued (Yu et al., 1986; Iwakuma et al., 1999).

Lentiviral vectors have been examined with respect to their potential elicitation of immune responses in the brain and within visceral organs. The data available indicate that in the CNS lentiviral vectors are minimally immunogenic, if optimized vector production and purification protocols are followed (Baekelandt et al., 2003). Systemic immunization preceding injection of lentiviral vectors into the CNS determined that pre-existing anti-lentiviral immunity, regardless of the transgene, did not affect transgene expression (Abordo-Adesida et al., 2005). Furthermore, Abordo-Adesida and colleagues showed that the transgene, but not the virion or vector components, is chiefly responsible for providing antigenic epitopes to the activated immune system, following systemic immunization with lentivirus.

Even though they are more limited in number, rodent and non-human primate studies performed to date have shown that rHIV vectors encoding for glial cell line-derived neurotrophic factor (GDNF) provide robust functional and structural neural protection in models of PD and provide an encouraging approach for gene therapy. Kordower and colleagues injected lentiviral vectors expressing GDNF into the striatum and substantia nigra of nonlesioned aged rhesus monkeys and young adult rhesus monkeys treated 1 week prior with the PD symptom-inducing neurotoxicant, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) (Kordower et al., 2000). Treatment with these vectors augmented dopaminergic functioning and reversed a set of behavioral deficits. More recently, Brizard et al. were able to utilize a similar GDNF-expressing lentiviral vector to demonstrate functional reinnervation from remaining dopaminergic nerve terminals in the 6-hydroxydopamine (6-OHDA) rat model of PD (Brizard et al., 2006).

Lentivirus vectors have also been used in the development of potential AD therapeutics. Dodart and colleagues recently delivered varying alleles of the apolipoprotein E (apoE) gene,

which encodes for a lipid-binding protein with A β fibrillogenesis modulation activity, to AD mouse models to determine if expression of different alleles led to differential amyloid deposition (Dodart et al., 2005). Lentiviral delivery of the ϵ 4 allele, one that is believed to enhance the risk of human AD, led to increased A β deposition as measured by immunocytochemistry and ELISA. Conversely, lentiviral vector-mediated expression of the ϵ 2 allele resulted in a significant reduction in amyloid burden, which is suggestive of a potent dominant negative effect of apoE2 over mouse apoE on brain A β deposition. These findings are exciting but more experimentation is warranted to determine the actual biological function of apoE and how modulation of its activity could alter normal physiology.

48.3.5. Herpes Simplex Virus Vectors

Herpes simplex virus type 1 (HSV-1) is a naturally neurotropic virus capable of establishing latent infection within neurons, but also possesses the ability to infect a wide range of cellular targets. The cellular receptors responsible for virion docking and uptake have been cloned, including the herpesvirus entry mediator A (HveA) and HveC (nectin-1; (Montgomery et al., 1996; Hsu et al., 1997; Kwon et al., 1997; Geraghty et al., 1998; Warner et al., 1998)). Not surprisingly, these receptors (or homologues) are expressed on a variety of cell types. The HSV life cycle involves long periods of latency, and to that end, the virus has evolved a number of elaborate and highly efficient mechanisms to avoid detection and elimination by immune cells (Banks and Rouse, 1992). These properties have led to the development of two forms of HSV-1-based delivery vectors capable of *in vivo* and *in vitro* gene transfer to the nervous system: recombinant and amplicon vectors (Dobson et al., 1990; Breakefield and DeLuca, 1991; Andersen et al., 1992; Breakefield et al., 1992; Fink et al., 1992; Wolfe et al., 1992; Glorioso et al., 1994; Andersen and Breakefield, 1995).

48.3.5.1. HSV Recombinant Vectors

Recombinant HSV vectors comprise a wild-type HSV genome rendered replication defective via disruption/deletion of an indispensable viral gene(s). Typically, the immediate-early gene loci, which encode for potent transactivation proteins that initiate the viral lytic cycle, are targeted for insertion of therapeutic transcription units via homologous recombination (Marconi et al., 1996, 1999). Following construction, recombinant vectors are packaged into infectious virions using an engineered eukaryotic cell line that supplies the absent viral gene product(s) in trans (Dobson et al., 1990; Andersen et al., 1992). The genome of recombinant vectors, at present, can accommodate approximately 30kb of genetic material. Recombinant vectors are also attractive gene transfer vehicles for CNS disorders because they can be propagated to relatively high titers (10^8 – 10^9 plaque-forming units/ml). In addition, the threat of insertional mutagenesis is greatly diminished as the

vector genome persists episomally within post-mitotic cell nuclei.

Immune responses arising from infusion of recombinant HSV vectors can arise from any of the following sources: viral particle components, co-purified packaging cell debris, low-level *de novo* viral gene product expression, and transgene expression itself. What appears to be a major source of immune response elicitation is related to *de novo* expression of the intact viral transcription units. Recombinant HSV vectors, although replication-defective, harbor virtually intact segments of the HSV genome. These open reading frames (ORFs) are expressed at low levels even in the absence of immediate-early gene products, augmenting the potential for antigen processing and subsequent MHC Class I presentation (Johnson et al., 1992; Krisky et al., 1998). Detailed assessment of immune responses elicited against HSV recombinant vectors within the brain have been lacking. However, insights may be gleaned from studies employing the amplicon vector platform, which have received, immunologically speaking, more investigational attention.

48.3.5.2. HSV Amplicon Vectors

The HSV-1 amplicon is a uniquely designed eukaryotic expression plasmid that harbors two non-protein encoding virus-derived elements: an HSV origin of DNA replication (OriS) and the cleavage/packaging sequence ("a" sequence) (Frenkel, 1981, 1982; Spaete and Frenkel, 1982, 1985; Stow and McMonagle, 1982; Geller and Breakefield, 1988; Federoff et al., 1992; Geschwind et al., 1994). Both *cis* sequences are specifically recognized by HSV proteins to promote the replication and incorporation of the vector genome into viable viral particles, respectively. This highly versatile plasmid can be readily manipulated to contain desired promoters, enhancers, and transgenes of substantial size (~130kb) (Wade-Martins et al., 2001). Heterologous

transcription units either singly or in combination can be cloned into the amplicon plasmid using conventional molecular cloning techniques, and the resultant construct is packaged into enveloped viral particles for subsequent transduction of cells or tissues.

Amplicon plasmids are dependent upon helper virus function to provide the replication machinery and structural proteins necessary for packaging amplicon vector DNA into viral particles. An engineered replication-defective HSV derivative that lacks an essential viral regulatory gene has conventionally provided helper packaging function. These helper viruses are similar to the recombinant HSV vectors discussed above in that they retain a majority of the HSV genome. The final product of helper virus-based packaging contains a mixture of varying ratios of helper and amplicon virions. The titers obtained from helper virus-based amplicon packaging range from 10^8 to 10^9 expressing virus particles/ml. More recently, helper virus-free amplicon packaging methods have been developed by providing a packaging-deficient helper virus genome via a set of five overlapping cosmids or a bacterial artificial chromosome (Fraefel et al., 1996; Saeki et al., 1998, 2001; Stavropoulos and Strathdee, 1998). This packaging strategy requires the co-transfection of eukaryotic cells that are receptive to HSV propagation (i.e., BHK, Vero) with packaging-incompetent HSV genomic DNA, amplicon DNA, and any accessory HSV genes shown to enhance amplicon titers (Bowers et al., 2001) (Figure 48.1). Crude vector lysates are then purified by a series of ultracentrifugation steps and titered by expression or transduction-based methodologies (Bowers et al., 2000). The titers obtained from helper virus-free amplicon packaging typically range from 10^7 to 10^8 expressing virus particles/ml. The lack of contaminating helper virus in these stocks, and thus loss of immunosuppressive proteins like ICP47, has also made the HSV amplicon a powerful delivery platform for infectious disease and cancer

FIGURE 48.1. The helper virus-free method of HSV-1 amplicon packaging involves the use of a bacterial artificial chromosome (BAC) that contains the entire HSV genome minus its cognate cleavage/packaging signals [pBAC-V2; (Stavropoulos and Strathdee, 1998)]. Co-transfection of pBAC-V2, an accessory plasmid encoding HSV virion host shutoff protein (Bowers et al., 2001) and an amplicon plasmid, into a cell line permissible to HSV virion propagation (e.g., Vero, baby hamster kidney cells) results in stocks composed specifically of amplicon-containing virions that exhibit low, if any, cytotoxicity (Olschowka et al., 2003). Titers of stocks produced by this method range from 10^6 to 10^7 transducing units per ml with a very low wild-type frequency (<1 in 10^8).

vaccines (Tolba et al., 2001, 2002; Willis et al., 2001; Hocknell et al., 2002).

Similar to recombinant HSV vectors, immune responses arising from infusion of HSV amplicon stocks can arise from several sources and such responses are dependent upon the packaging system employed. Immune response-eliciting sources include viral particle components, co-purified packaging cell debris, low-level *de novo* viral gene product expression (helper virus-based packaging only), and the expressed transgene. Early generation helper virus-based packaging methods lead to vector stocks that contain substantive levels of contaminating helper virus. Due to the identical physical properties of amplicon and helper virus particles, preferential purification of amplicon particles is not possible. The replication-defective helper virus, comparable to the recombinant HSV vectors described above, expresses viral proteins at low levels within transduced cells. These viral proteins exhibit cytotoxic activity and can potentially undergo antigenic processing and subsequent immune presentation.

Wood and colleagues were the first investigators to examine the immune responses elicited against early iterations of packaged HSV amplicon stocks. For their studies they utilized an amplicon expressing the reporter gene product β -galactosidase and packaged using a recombinant HSV helper virus (*tsK*), which possessed a temperature-sensitive mutation in the ICP4 gene locus (Wood et al., 1994). Although *tsK* is replication-defective at the non-permissive temperature of 39° C, viral gene product-associated cytotoxicity remains observable. Administration of these amplicon stocks induced a vigorous inflammatory response. Elevated MHC Class I expression and microglial activation was evident by 2 days post-infection, which was followed by MHC Class II cell recruitment, T cell activation, and macrophage influx at 4 days following delivery of helper virus-contaminated amplicon stocks.

In a more recent study, our laboratory described the innate responses elicited upon stereotactic delivery of HSV amplicon vectors packaged via two different methods (Olschowka et al., 2003). C57Bl/6 mice were injected with sterile saline, β -galactosidase-expressing amplicon (HSVlac) packaged by a conventional helper virus-based technique, or a helper virus-free HSVlac preparation. Animals were sacrificed at 1 or 5 days post-transduction and analyzed by immunocytochemistry and quantitative RT-PCR for various chemokine, cytokine, and adhesion molecule gene transcripts. All injections induced inflammation with blood-brain barrier opening on Day 1 that was similarly enhanced following all treatments. By Day 5, mRNA levels for the pro-inflammatory cytokines (IL-1 β , TNF- α , IFN- γ), chemokines (MCP-1, IP-10) and an adhesion molecule (ICAM-1) had fully resolved in saline-injected mice and to near baseline levels in mice receiving helper virus-free HSVlac. In contrast, mice injected with helper virus-packaged amplicon stocks elicited elevated inflammatory molecule expression and immune cell infiltration even at Day 5. In aggregate, these studies demonstrated helper virus-free amplicon preparations exhibit a safer innate immune response pro-

file when delivered directly to the brain, presumably due to the absence of helper virus gene expression, and provide support for future amplicon-based CNS gene transfer strategies. What remains to be assessed experimentally in greater detail is the role, albeit minor, that virion structural components, packaging cell-derived debris, and transgene product appear to play in the activation of the innate immune response by helper virus-free amplicon stocks. In addition, the role of pre-existing HSV immunity in modulating host responses to brain-delivered HSV vectors remains understudied.

48.4. Neuroimmunotherapy

Awareness of brain “immunocompetence” has increased significantly in recent decades. Immunomodulatory molecules are expressed in the brain by microglia, astrocytes and neurons in the presence of an inducing stimulus, including the infusion of gene transfer vectors. Additionally, macrophages, T cells, and B cells traverse the blood-brain barrier and survey the brain as part of their normal physiologic function (Hickey, 2001). Furthermore, chronic activation of brain-resident inflammatory processes has been shown to underlie the pathophysiology of several neurodegenerative diseases such as Alzheimer’s disease (AD) and Parkinson’s disease (PD). One of the central features of AD is the excessive accumulation of amyloid beta (A β_{1-42}), a 42-amino acid peptide, in extracellular senile plaques. Moreover, the AD brain is decorated with complement proteins that bind to A β peptides and aid in opsonization for eventual clearance by microglia. In response to accumulating A β , microglia in the AD brain express an array of potent cytokines and chemokines that are likely neurotoxic and may contribute to cell loss (Strohmeier and Rogers, 2001; Hanisch, 2002; McGeer and McGeer, 2003).

Inflammatory processes may also contribute to the degeneration observed in PD brain. PD is characterized by the destruction of dopamine-containing neurons in the substantia nigra (SN), resulting in a loss of dopaminergic afferents to the basal ganglia and eventual motoric dysfunction (Olanow, 2003; Olanow et al., 2003). Pathologically, PD brain exhibits a region-specific accumulation of Lewy bodies, which are intraneuronal inclusions comprised of aggregated α -synuclein and other cellular proteins (Hald and Lotharius, 2005). A variety of pro-inflammatory mediators have been detected in human PD and animal models of the disease (reviewed by McGeer and McGeer, 2004). Moreover, epidemiological evidence has shown that chronic treatment with nonsteroidal anti-inflammatory drugs (NSAIDs) reduces the risk of AD and PD compared to those who take NSAIDs on a non-regular dosing regimen (Schiess, 2003; Standridge, 2004). While it appears that numerous cytokine and chemokine molecules are closely associated with and likely contribute to neurodegeneration in AD and PD, it is uncertain whether these inflammatory mediators impart beneficial effects during pathogenesis.

A promising, yet inherently complex, means of preventing A β accumulation in AD or α -synuclein in PD relates to the use of the host immune system to mount specific immune responses against the self-peptides, A β and α -synuclein (Klyubin et al., 2005; Masliah et al., 2005). The findings from a variety of immune-based strategies speak to the promise of such approaches, but also reveal the potential for morbid complications, especially in the case of AD vaccination. Therefore, it is imperative that as immunotherapeutics are designed to prevent and/or treat neurodegenerative diseases the underlying inflammatory processes are taken into account.

48.4.1. Immunotherapeutic Approaches to Treating Neurodegenerative Diseases

Two principal immunotherapeutic strategies for diseases afflicting the CNS have been pursued: passive and active vaccine-based approaches. Passive immunization involves the transfer of antiserum, purified antibodies, or an antibody-encoding gene via gene delivery to a recipient to prevent the accumulation of or to promote the removal of a central pathogenic factor. For example, passive immunization achieved by administration of A β -specific antibodies has shown promise in preclinical studies. The laboratories of Drs. Holtzman and Ashe have independently reported the benefits of systemic delivery of A β -specific antibodies to AD mice (Dodart et al., 2002; Kotilinek et al., 2002). Treated mice exhibited a marked reduction in amyloid accumulation and a significant improvement in memory-oriented behavioral tests. Using a similar passive immunization approach, Bard et al. showed that peripherally administered monoclonal antibodies against the A β enter the CNS of PDAPP mice (Bard et al., 2000). Additionally, these passively administered antibodies promoted the clearance of pre-existing amyloid, thus reducing the plaque burden. Prophylaxis against amyloid pathology required multiple injections of high-titer antibody in all studies. Approaches that provide for the stable production of A β -specific antibody *in situ*, such as via gene transfer, may represent a more viable therapeutic option.

48.4.2. Single Chain Antibodies as Passive Immunotherapeutics

One gene-based passive vaccination approach that may serve in this capacity involves the use of single-chain antibodies (scFv's). ScFv's are composed of the minimal antibody-binding site formed by non-covalent association of the V_H and V_L variable domains joined by a flexible polypeptide linker. Human scFv-phage libraries are available and allow for high affinity human scFv antibodies to be selected from combinatorial libraries. Thus far, phage display has proven to be a powerful tool for rapidly generating and isolating recombinant antibodies. Selection by phage display entails binding of phage populations expressing antibody molecules on the tip of the phage particle to a specified antigen (i.e. α -A β peptide).

The antigen is immobilized on a microtiter plate well, incubated with phage and then washed to remove non-specifically bound phage. Phages are eluted from antigen, re-expanded and the entire process is repeated for several more cycles, a process termed "panning." At each cycle, the fraction of specifically bound phage increases while the diversity of antibody sequences decreases until the population consists of only phages that can bind antigen with roughly equivalent panning efficiencies (Malone and Sullivan, 1996). The phage clones identified with strong affinity to the target antigen are then amplified in *E. coli* (Haidaris et al., 2001).

Sequences encoding eukaryotic secretion signals (i.e., kappa light chain leader) can be appended to the scFv genes and subsequently be cloned into gene transfer vectors. Cells transduced by a given gene transfer vector will act as a nexus of scFv expression, leading to a gradient of secreted scFv to act extracellularly on pathogenic factors such as A β . Single-chain antibodies are also being investigated for prion disease therapy as a single-chain has been developed that binds to PrP^C and inhibits prion replication (Leclerc et al., 2000; Peretz et al., 2001). Further antibody engineering makes it possible to manipulate the genes encoding these antibodies to allow for expression *within* mammalian cells. Genetically fusing the scFv to intracellular targeting signals allows for specific subcellular expression (Zhu et al., 1999). These intracellular antibodies, termed intrabodies, are capable of modulating target protein function in at least three important ways. Intrabodies can: (1) block or stabilize macromolecular interactions; (2) modulate enzyme function by sequestering substrate, occluding an active site or keeping the enzyme in an active or inactive conformation; and (3) divert proteins to alternative intracellular compartments (for review Richardson and Marasco, 1995). Intrabodies have been utilized for both phenotypic and functional knockouts of target molecules. For example, scFv's directed against the extracellular domain of ErbB-2 fused to an endoplasmic reticulum (ER) signaling domain have been expressed intracellularly and successfully target to the ER lumen. These targeted scFv's were capable of binding newly synthesized ErbB-2 and preventing its transit through the ER to the cell surface resulting in functional inactivation of this protein (Beerli et al., 1994).

Perhaps most relevant to the proposed use of scFv's for a neurological disorder is the recent work from Lecerf et al. (2001). This group identified human scFv intrabodies capable of interacting *in situ* with huntingtin and reducing its aggregation. These scFv's were bound to the N-terminal residues of huntingtin and kept the normally aggregated protein in a soluble complex that then underwent normal protein turnover. Specificity of binding was further determined by fusing the anti-huntingtin scFv with a nuclear localization signal and the subsequent retargeting of soluble huntingtin to cell nuclei. This strategy is currently being used for Parkinson's disease (PD) where single-chains targeted against synuclein are hypothesized to halt the oligomerization and formation of toxic oligomeric species (K. Maguire-Zeiss,

personal communication). Given the relatively short half-life of scFv's *in vivo* [<0.7 – 14 h depending upon the absence or presence of stabilizing agents, respectively; (Chapman, 2002)], the use of integrating viral vectors that exhibit long-term gene expression can provide the means to offer continuous passive immunization for neurodegenerative diseases with underlying abnormal protein accumulation/aggregation.

48.4.3. Active Vaccination

In contrast to passive means of preventing pathogenic protein accumulation in the CNS, active immunization involves using antigen to stimulate the host to produce vigorous immune responses, including the elicitation of antibodies and cytotoxic cells. This more conventional immunization method is many times preferable since long-term immune memory to a specific antigen can be readily maintained.

Recent publications have highlighted the potential of active A β peptide-based immunization in the treatment of AD (Schenk et al., 1999; Janus et al., 2000; Morgan et al., 2000). Schenk et al. used a transgenic model that overexpresses a mutant APP (V717F) mini-gene driven by the platelet-derived growth factor promoter (PDAPP; (Schenk et al., 1999)). PDAPP mice immunized and boosted with A β_{1-42} peptide with complete and incomplete Freund's adjuvant, respectively, before the onset of AD-like pathology, were protected from development of plaque formation, neuritic dystrophy, and astrogliosis. Treatment of older PDAPP animals (11 months) with existing pathology resulted in reduced plaque burden and slower progression of AD-like neuropathology. A β -directed vaccination was assessed by other laboratories in a model of AD that overexpresses mutant human β APP₆₉₅ (K670N/M671L; Swedish mutation) and PS1 mutations under the control of the hamster prion promoter (PSAPP) (Morgan et al., 2000; Takeuchi et al., 2000). Neuropathologically, these animals demonstrate compact amyloid plaques but no dramatic neuronal loss in either the hippocampus or association cortices. Behaviorally, PSAPP mice exhibit learning and age-related memory deficits as amyloid accumulates. Following vaccination with A β , PSAPP mice were protected from learning and age-related deficits as well as a partial reduction in amyloid burden. There were no apparent deleterious effects of the vaccination.

These groundbreaking studies provided impetus for the implementation of Phase I and II clinical trials where human aggregated A β and a potent adjuvant (QS-21) was used to immunize individuals with advanced AD. While some of the patients enrolled in the Phase II trial generated anti-A β antibody titers (Lee et al., 2005), the trial was halted due to the occurrence of aseptic meningoencephalitis in a subset of responders (based on the antibody titer) and non-responders. Postmortem analyses of two patients that died showed that the encephalitic response was characterized by infiltrating CD4 cells but not CD8s, giant nucleated cells, or macrophages (Ferrer et al., 2004; Gilman et al., 2005). Most intriguing was the observation that these brains harbored low A β plaque

load strongly suggesting that active A β immunization could alter A β accumulation patterns (Nicoll et al., 2003). This trial not only demonstrated that immunization against A β may be effective but underscored the requirement that AD vaccines require fine-tuning to greatly diminish the likelihood of eliciting brain inflammation.

48.4.4. Immune Shaping: Th1 and Th2 Responses and Antibody Isotypes

A successful immune response against a pathogenic entity as induced by active vaccination, such as in the case of an amyloid-containing plaque in AD, must include at least four major features. These include recognition of the antigens unique to the plaque; induction of the correct effector mechanisms to dissolve the plaque; mobilization of the response in the correct location; and protection of surrounding CNS tissue from excess immune-mediated damage. Different phenotypes of CD4 T cells secreting distinct cytokine patterns have a major role in regulating the type of immune effector functions deployed against pathogens, and protecting host tissues against damage. Th1 cells secrete IL-2, IFN γ , and lymphotoxin and are most useful against intracellular pathogens that are best attacked by a cell-mediated response involving macrophage and granulocyte activation (Sher and Coffman, 1992). Th2 cells secrete IL-4, IL-5, and IL-10, and induce antibody and allergic responses that are useful for combating infections (Finkelman et al., 1997). Although the Th1/Th2 dichotomy is important in a number of mouse and human diseases, several other T cell cytokine secretion phenotypes also exist. Th0 cells secrete both Th1 and Th2 cytokines. Th3 cells (secreting TGF β ; (Chen et al., 1994)), and Treg1 cells [secreting IL-10 but not IL-4; (Groux et al., 1997)] inhibit Th1 responses, and may suppress inflammatory responses that would otherwise cause excessive tissue damage during infections or autoimmunity. CD4 T cells may also remain in an uncommitted state even after activation and proliferation in response to antigen (Sad and Mosmann, 1994; Akai and Mosmann, 1999; Sallusto et al., 1999). These primed precursor cells continue to express IL-2 but not other cytokines, and retain the ability to differentiate into either Th1 or Th2 cells. This expanded pool of antigen-specific cells might then differentiate rapidly in subsequent infections to provide the correct effector functions. In addition to attacking the pathogen, a successful immune response must include regulatory mechanisms that limit damage to host tissues. For example, during *Toxoplasma* infection in mice, IFN γ is required to defeat the pathogen (Scharton-Kersten et al., 1996), and IL-10 is required to protect the host from an excessive, lethal Th1 response (Gazzinelli et al., 1996). For both mouse and human T cells, IL-4 induces differentiation of naïve CD4 T cells into Th2 cells, and IL-12 induces differentiation of naïve CD4 T into Th1 cells (Seder and Mosmann, 1999). IFN γ also enhances Th1 differentiation, at least partly by enhancing expression of the IL-12 receptor β 2 chain. Once differentiated, the Th1 and Th2 effector

phenotypes are relatively stable, and so it is difficult to subsequently convert a strongly polarized immune response to a different set of effector functions.

In parallel with the diversity of T cell responses, several antibody responses are possible. The specificity of the antibodies for different antigens, or different epitopes on the same antigen, can markedly affect the usefulness of the antibodies, and the isotype of the antibodies is also important. Under the regulation of T cells and other cytokines, B cells switch to the production of IgA, IgE, or different subsets of IgG, all with unique sets of functions. IgE initiates allergy via triggering of degranulation from mast cells, IgA is selectively secreted at mucosal surfaces, and IgG1 and IgG3 (human) or IgG2a (mouse) are the major isotypes that fix complement and opsonize cells for phagocytosis by macrophages.

48.4.5. Evaluating an Appropriate Active Vaccine Response for Alzheimer's Disease

The ability of APP peptide immunization to reduce plaque formation and improve memory behavior (Schenk et al., 1999; Janus et al., 2000; Morgan et al., 2000) may be explained by solubilization of the protein precipitates by binding of antibody. If this simple model is correct, then an ideal vaccine for Alzheimer's disease should induce a strong antibody response, mainly of isotypes that can cross the blood/brain barrier. Helper T cell function, normally required for a good antibody response, should be limited to Th2-biased responses, because a strong Th1 response carries the risk of inducing a local inflammatory response to the APP antigen, if T cells penetrate the blood/brain barrier for any reason. CTL responses would also be undesirable for similar reasons. In contrast, a concurrent Th3/Treg1 response including TGF β and IL10 synthesis might be desirable, as these cytokines would help to control any inflammatory response that might develop. Complement activation by antibody/antigen complexes may have either useful or deleterious effects—complement deposition may help to solubilize antigen/antibody complexes that develop in the plaques as a result of antibody binding (Miller and Nussenzweig, 1975), but complement activation may also initiate inflammation. Recruitment of macrophages may also enhance solubilization of precipitates or immune complexes, but activation of the macrophages may lead to local inflammation and tissue damage. It appears as though at least a subset of these negative immune outcomes were at play in the AN-1792 Phase II human clinical trial.

Despite this initial clinical setback, A β -directed active vaccination continues to warrant further assessment via careful step-wise refinement and testing of novel immunotherapeutic approaches. It is clearly important to evaluate the antibody isotypes that are induced by candidate vaccine constructs, as well as determining the types of CD4 and CD8 T cell immunity that are elicited. This information will undoubtedly facilitate the design of safer active vaccination strategies to direct the resultant immune response towards more desired effector functions.

48.5. Future Outlook

The future of gene-based immunotherapy for neurological disease remains mired in many unknowns. The most informed choice of vector platform, gene regulation system, and immunotherapeutic strategy will depend on numerous non-mutually exclusive factors: the specific neurodegenerative disease, the disease stage, the underlying inflammatory mechanisms associated with the disease, the interplay between those events and those inherent to the proposed vector systems following CNS delivery, and the therapeutic transgene itself. Another major challenge that faces this field involves the heterogeneity of human immune responses. For example, why did only a subset of individuals enrolled in the AN-1792 Phase II clinical trial present with an encephalitic condition while a majority of others did not? These adverse events may have occurred due to the differing immune profiles of each patient and not specifically a result of disease stage or circulating anti-A β antibody titers or isotypes. It is therefore imperative that research continues to be conducted in the area of immune profiling in order to derive highly sensitive measures that are predictive of potential adverse immune-related symptoms. This would facilitate pre-screening of clinical trial participants and may allow for the derivation of custom immunotherapies based on a given patient's immune profile (O'Toole et al., 2005; Rosenberg, 2005). These considerations will be important in the conceptual design and the clinical implementation of gene-based immunotherapeutics for diseases afflicting an organ system formerly regarded, and unfortunately so, as an immunoprivileged region of the human body.

Summary

Clinical implementation of gene-based therapeutics and immunotherapeutics for prevention and/or amelioration of human neurologic diseases eventually will be realized, but this goal inherently presents a series of significant challenges, one of which relates to issues of immune system involvement. Devising gene therapeutics for the diseased central nervous system is particularly challenging from a neuroimmunological perspective given that many targeted neurologic disorders possess an underlying inflammatory component. Presently, direct gene-based delivery to the brain requires invasive surgical procedures and a majority of the gene delivery platforms incite transient, and sometimes, inflammatory events that have the potential to exacerbate disease-related processes. Moreover, peripheral administration of a gene-based immunotherapeutic designed to target pathologic antigens within the brain also carry the untoward potential to amplify extant disease-related inflammation. Studying the immunobiology of viral and nonviral gene delivery platforms in the context of the neurodegenerative condition is therefore imperative to fully appreciate the inflammatory mechanisms at play and

provide potential avenues to prevent and/or counter adverse anti-vector immune responses.

Review Questions/Problems

Note: For the following multiple choice questions, there may be more than one correct answer.

You have been recently hired as a consultant at a reputable biotechnology company that develops novel therapies for Sly Syndrome, a lysosomal storage disorder, caused by the absence of an enzyme called β -glucuronidase. Individuals lacking this enzyme exhibit a progressive accumulation of lysosome-harbored undegraded glycosaminoglycans, leading to mental retardation, loss of hearing and vision, joint abnormalities, and enlargement of the liver. This company wants to pursue a gene therapy-based approach to treat the central nervous system-related symptoms of the disease. The stipulations in the company's directive are that the therapy be long lasting (>2 yrs, but preferably life-long), directed to neurons, and be safe and effective. The vector platform the company will eventually pursue needs to effectively deliver a neuron specific enolase (NSE) promoter-driven β -glucuronidase transcription unit (~7 kb in total size). Given your expertise in employing several virus-based gene therapy vector types for *in vivo* applications, you form an opinion on how the company should proceed.

1. Which of the following vectors would be able to carry the designed transcription unit?
 - a. HSV amplicon vector
 - b. Recombinant AAV vector
 - c. Lentivirus-based vector
 - d. Adenovirus-based vector
 - e. All of the above
2. Which of the following vectors would be most appropriate for this disease application given the description shown above?
 - a. HSV amplicon vector
 - b. Recombinant AAV vector
 - c. Lentivirus-based vector
 - d. Adenovirus-based vector
3. Select the viral vector(s) that would be able to harbor a 2 kb transcription unit?
 - a. Adenovirus vectors
 - b. Adeno-associated virus vectors
 - c. Murine oncoretrovirus vectors
 - d. Lentivirus vectors
 - e. Recombinant HSV vectors
 - f. HSV amplicon vectors
4. Select the viral vector(s) that would be able to harbor a 15 kb transcription unit?
 - a. Adenovirus vectors
 - b. Adeno-associated virus vectors
 - c. Murine oncoretrovirus vectors
 - d. Lentivirus vectors
 - e. Recombinant HSV vectors
 - f. HSV amplicon vectors
5. Which of the following considerations takes into account transcriptionally regulating what cell type a particular transgene is expressed within?
 - a. Focal tissue delivery
 - b. Promoter selection
 - c. Transgene glycosynthesis
 - d. Trypan blue
 - e. Virus tropism
6. Which of the following viral vector(s) delivers a genome that is episomally maintained in the transduced host cell nucleus?
 - a. Adenovirus vectors
 - b. Murine oncoretrovirus vectors
 - c. Lentivirus vectors
 - d. Recombinant HSV vectors
 - e. HSV amplicon vectors
7. Which of the following viral vector(s) delivers a genome that integrates in the transduced host cell genome?
 - a. Adenovirus vectors
 - b. HSV amplicon vectors
 - c. Lentivirus vectors
 - d. Replication-restricted HSV vectors
 - e. Recombinant HSV vectors
8. Delivery of viral vectors *in vivo* presents a series of safety and immunological concerns. Name the source(s) of each of the potential dangers that can arise.
9. Name the two non-coding sequences derived from HSV that are included in HSV amplicon vectors.
10. What is a single-chain antibody?
11. What is the difference between active and passive immunization?
12. Based upon the scientific data available at present, what would be the ideal immune responses elicited by a vaccine for Alzheimer's disease?

49.1. Introduction

Successful completion of sequencing of the human genome showed considerably smaller number of genes (20,000 to 25,000 protein coding genes) (International Human Genome Sequencing Consortium. Lander ES, 2004) than expected and the number of proteins greatly exceeding the number of genes. This had a big impact on how we envision human and other proteomes and how we will approach proteomic and genomic analyses in the future. Isoforms, products of one gene modified by posttranslational modifications or alternative splicing, is only one part of complexity because function and biological role can also depend on cytoplasmic, subcellular compartments, and/or extracellular localization. Interactions with other proteins and nonproteinaceous molecules add yet another layer of complexity.

49.2. Proteomics and Genomics—Technologies for Global Oversight of Complex Biological Systems

Proteomics as a scientific field emerged in mid-1990 along with technological advances in analysis of proteins and peptides. Two-dimensional polyacrylamide gel electrophoresis (2D SDS-PAGE) originally developed in late 70s (Barritault et al., 1976) rapidly advanced to the next level when immobilized pH gradient (IPG strips) gels were introduced (Gelfi and Righetti, 1983) facilitating analysis of gene products containing over 2,000 proteins in a mixture (Gianazza, 1995) with much higher reproducibility. Mass spectrometry of proteins and peptides is developing fast and providing new meth-

ods and reagents for quantitative analysis such Isotope Coded Affinity Tags (ICAT). Recently, protein microarrays have emerged, adding yet another powerful tool in global screening of gene products in complex biological systems. Development of user friendly kits for protein sample preparation and extraction enabled nonprotein chemists to isolate proteins, fractionate complex samples, and develop their own protocols in a similar way as development of expression vectors and systems (Feuerstein et al., 2005). Growth of all kind of databases, new and improved algorithms for database searches opened the door for high throughput experiments with substantially increased quality of protein identification and quantitative measurements (Ku and Yona, 2005). Thus it became a reality to identify fingerprints of changes induced by infection, malignant transformation, exposure to toxic agents, or differentiation (Pang et al., 2006). Therefore, substantial progress in prognosis and monitoring of disease progression and discovery of new biomarkers and drug targets is widely expected.

Until now proteomic analysis delivered less than expected new drug targets and biomarkers. Nevertheless, proteomic approach made it possible to accumulate unprecedented amounts of new and original data within a short period of time, which on the other hand, created demand for better and faster tools for data analysis. Another issue is how to manage such large amounts of data and information and how to navigate, for example, through thousands of collected spectra. In response to this demand, Laboratory Information Management Systems (LIMS) became commercially available, yet smaller laboratories in many instances cannot afford expensive softwares and high capacity servers to fully utilize medium to high throughput proteomic analysis.

Advancement in high throughput technology in proteomics and genomics led to studies of systems biology (for definition http://en.wikipedia.org/wiki/Systems_biology), meaning to monitor changes of thousands of individual components within the system at the same time. Thus, top-down approach deals with system modeling leading to hypothesis, prediction, and simulation of behavior of an organism under various physiological conditions. Bottom-up approach will study

individual pieces on a discovery basis and combine all the information to understand how the system in question works (Figure 49.1).

The same concept in proteomics studies has technological implications, e.g., which method, sample preparation protocols, and instrumentation will be used. Again, top-down analysis will be based on isolation, analysis, and characterization of an intact protein to reveal its function. Fourier transformed ion cyclotron resonance mass spectrometry (FT-ICR) (Marshall et al., 1998) facilitates such approach in protein identification as a result of random fragmentation of an intact molecule. In contrary, bottom-up approach is based on up-front fragmentation of the protein in question using various proteolytic enzymes with known specificity (Chalmers et al., 2005; Millea et al., 2006). In these experiments, trypsin is most commonly used. An important question that remains is whether more

information will be obtained from bottom-up approach, which is protein identification on a cost of protein characterization, or from top-down approach, which is distinguishing differences between two similar proteins/isoforms. Of course, the ideal situation is to obtain both answers from one type of analysis. Handling mixtures of peptides generated from complex a protein mixture (bottom-up approach) will be very different from sample processing at the protein level prior to analysis (top-down approach). Therefore, integration of these two will be a technological challenge in coming years because to make significant contributions, both approaches will require collaboration of scientists with diverse expertise with cross-disciplinary nature.

Regardless of the approach, bottom-up or top-down, cells, their compartments and organelles (nucleus, mitochondria, endosomes etc.) as well as body fluids are complex and dynamic systems comprising of multiple networks of interacting

FIGURE 49.1. Top-down and bottom-up approach in studying systems biology. There are three components contributing equally to study biology systems: theoretical, conceptual, and experimental approaches. All of these approaches more and more heavily depend on implementation of effective bioinformatics tools. Hypothesis driven and discovery driven project equally participate in studying systems biology.

molecules of various natures: proteins, glycoproteins, glycolipids, nucleic acids, metabolites etc. An overview, moreover understanding of these components and their mutual interactions and communications, requires specific bioinformatics tools which start emerging. This issue is further amplified by the amount of data/information accumulated in every experiment of a high throughput analyses. Full understanding of interactions between different types of molecules such as DNA, RNA, and proteins in any biological system will require coordination of multiple experimental techniques at the same time which will either require more sample or reduction of sample size for each individual test. Development of application of microfluidics in new analytical instrumentation will definitely facilitate miniaturization efforts in proteomics.

Gene array techniques and gene sequencing which have been used in studying biological systems for many years provided enormous amount of valuable information, just to mention the completion of Human Genome Project (International Human Genome Sequencing Consortium. Lander ES, 2004). Gene arrays are also much more mature technology, with Affymetrix as a leader in this category, than those used in proteomics (Reimers et al., 2005). This technology platform is easy to use in variety of experimental designs and it is the best standardized among other systems. Gene arrays, similarly to proteomic profiling, struggles with reproducibility and number of false positive results (Reimers et al., 2005). Proteomics, on the other hand, offers a number of additional and unique benefits. For example, proteins which are functional products of an

expressed gene can be posttranslationally modified, and their subcellular localization can be altered in a different physiological state. This important information cannot be obtained using gene arrays.

Results from studies of biology systems lead to the conclusion that individualized diagnosis, clinical evaluation, and treatment will be inevitable. In many instances, amount of sample available for diagnostic purposes is and will be limited demanding more sensitive techniques and instrumentation on one hand, and development of single cell analysis on the other hand. Automated and simple steps of sample processing combined with highly sensitive and specific measurements will improve what currently contributes to loss of important markers in a limited sample.

49.3. Proteomics Technologies

New and improved technologies are being developed to address important issues in proteomics as a global overview of protein makeup (Rohlff and Southan, 2002; Petricoin and Liotta, 2003). Increasing resolution, sensitivity, speed of analysis (high throughput), and reproducibility are the major areas of concurrent improvements. Summary of technologies most commonly used in proteomics is presented in Table 49.1.

2D SDS-PAGE which combines two modes of separation: isoelectric focusing and polyacrylamide gel electrophoresis has been on the market for about 30 years (O'Farrell, 1975; Barritault et al., 1976). Initially this technique did not gain much of popularity due to obstacles in part originating from poor

TABLE 49.1. Summary of analytical and preparative methods most commonly used in proteomic studies.

Method	Description	Applications
SDS PAGE	Fractionation based on approximate molecular weight (m.w.).	Preparative/analytical
IEF	Fractionation based on isoelectric point (pI).	Preparative/analytical
2 D electrophoresis (IEF/SDS PAGE)	High resolution separation/fractionation based on pI and m.w., long and complex procedure.	Preparative/analytical
Capillary electrophoresis (CE)	Fractionation based on m.w. or pI, possible direct connection to MS.	Preparative/analytical
HPLC/FPLC	Fractionation based on physico-chemical features of protein (m.w., pI, hydrophobic profile).	Preparative/analytical
SELDI-TOF	Fractionation based on selective binding to activated surfaces followed by MS determination of m.w., automatic fast sample processing combined with mass spectrometry.	Analytical
Protein arrays	Identification/separation techniques based on protein-protein interactions including antigen-antibody interactions.	Analytical
LC-MS/MS	Chromatographic one or two dimensional fractionation followed by mass spectrometric peptide sequencing and protein identification.	Analytical
MALDI-TOF	Requires high resolution mass spectrometry for protein identification based on peptide fingerprinting.	Analytical

reproducibility. It was also not very suitable method for typical routine analyses (Jellum and Thorsrud, 1986) and remained as research tool until early 90s. Development of immobilized pH gradient (IPG) strips made this method much more user friendly, and most importantly, much more reproducible. This allowed creation of computerized protein databases based on two-dimensional separation (Celis et al., 1990). Although the resolution, thus reproducibility, of 2D SDS-PAGE remains a limitation especially in high molecular mass range or for hydrophobic proteins, advancement in protein sequencing by electrospray ionization-mass spectrometry/mass spectrometry (ESI-MS/MS) made possible to identify proteins directly from the protein "spots." Matrix Assisted Laser Desorption Ionization Time-of-Flight (MALDI-TOF) fingerprinting is another approach for protein identification from a mixture of tryptic digested proteins. Further on, development of specialized softwares for analysis of 2D SDS-PAGE gels facilitated automated comparison and quantitation of experiments consisting of multiple gels with large number of proteins separated in a single separation. A disadvantage of 2D SDS-PAGE such as concurrent analysis of high and low molecular weight proteins can be overcome by using a combination of various technologies. This aspect of proteomic analysis is discussed in more detail below in a paragraph describing hyphenated techniques (methods). Difference Gel Electrophoresis (DIGE) from GEHealthcare/Amersham, Inc. is another example of further technological advances. Two samples, one is labeled with 1-(5-carboxypentyl)-1'-methylindodi-carbocyanine halide N-hydroxyl-succinimidyl ester (Cy 5) while the other sample is labeled with 1-(5-carboxypentyl)-1'-propylindodi-carbocyanine halide N-hydroxyl-succinimidyl ester (Cy 3) fluorescent dyes. Next, these two samples are mixed together and analyzed in one 2D SDS-PAGE experiment. Common proteins are represented by yellow spots while differentially expressed proteins are represented by different color spots detected with laser based scanner.

Another tool for protein profiling is Surface Enhanced Laser Desorption Ionization Time-of-Flight (SELDI-TOF) (Weinberger et al., 2000; Purohit et al., 2006). This technology utilize MALDI-TOF mass spectrometer as a detection mode and one step chromatography by utilizing proprietary Protein Chips (Ciphergen, Inc.) to reduce complexity of analyzed sample. It is an analytical tool with relatively low resolution and mass accuracy in addition to high variability of intensities. Nevertheless, a big advantage of this method is ease of use for fast screening as compared to, e.g., 2D SDS-PAGE, which requires larger amounts of a sample for analysis. Another advantage of SELDI-TOF is information regarding properties and conditions of binding of proteins of interest to ion-exchange, hydrophobic, IMAC, and/or normal phases which can be utilized with success in translation to preparative methods using corresponding HPLC column (Enose et al., 2005). This technology is also susceptible to relatively high variability in analyses of multiple SELDI-TOF spectra. Jeffries et al. (Jeffries, 2005) developed an algorithm which

greatly improved spectra alignment thus improved reproducibility. MALDI-TOF instruments with higher resolution than SELDI-TOF combined with various chromatographic techniques has been also used but did not produce convincingly better results than SELDI-TOF (Coombes et al., 2005). Other mass spectrometers, such as FT-ICR are currently being evaluated for better reproducibility (Johnson et al., 2004).

Other technology platforms used for protein profiling include 2-dimensional HPLC, capillary electrophoresis interfaced with mass spectrometry, tissue profiling and imaging mass spectrometry (Reyzer et al., 2004; Caldwell and Caprioli, 2005), and a combination of IEF (chromatofocusing) in the first dimension followed by reverse-phase high performance liquid chromatography (RP-HPLC) (ProteomeLab PF 2D from Beckman Coulter, Inc.) (Billecke et al., 2006; Soldi et al., 2005). The ProteomeLab PF 2D workstation seems to be a promising alternative to 2D SDS-PAGE because it offers direct connection to an electrospray source of ESI-MS instrument or direct deposition onto MALDI-TOF target (Sheng et al., 2006; Shin et al., 2006). It has been proposed to complement already used profiling methods (Soldi et al., 2005). It may take some time, however, until these methods become more mature and reliable and will gain broader interest in the field of proteomics.

Multidimensional fractionation combined with removal of most abundant proteins is an essential step in detecting low abundant proteins in complex samples, in particular serum, plasma, or cerebrospinal fluid (CSF) (Chromy et al., 2004; Fountoulakis et al., 2004; Ramstrom et al., 2005). Recently published report of Human Proteome Organization (HUPO) Human Plasma Protein Project (HPPP) showed that almost all laboratories participating in this international effort used some mean of sample pre-fractionation. Eventually, 3,020 proteins were included in a database set from 15,677 proteins reported (Omenn et al., 2005). The same approach applies to biomarker discovery based on SELDI-TOF analysis. HPLC pre-fractionation of cell lysates using various columns enhanced sensitivity and specificity of SELDI-TOF determinations. Ciphergen Inc. (Freemont, CA), SELDI-TOF manufacturer recognized the necessity of pre-fractionation and developed spin columns for that purpose. Although such approach seems to be very attractive, it should be used with caution. Fractionation may significantly increase number of samples to be tested substantially increasing costs and time for data analysis.

Recent fast development of nanotechnology not only in drug delivery but also in diagnostics and monitoring combined with the technological boom of miniaturization made it possible to use lower amounts of sample for analysis and sustain at the same level of sensitivity and specificity. Single cell analysis is becoming a reality, although we have to be aware that not all proteins or their modified forms can be effectively detected at this level (Zhang et al., 2001; Diks and Peppelenbosch, 2004). Unlike in genomics, proteomics approach does not have luxury of *in vitro* amplification of proteins. Besides improving the yield of protein of interest

during sample preparation, detection limits in laboratory tests lowered by using multi-layered ELISA type of assays in which secondary antibodies labeled with enzyme bind at higher numbers to primary antibodies reacting in 1:1 ratio with specific epitope (Kim et al., 2005). This of course carries a risk of increased background, but for example chemiluminescent detection systems increased sensitivity of western blot analysis by more than order of magnitude comparing to color based detection systems (Sandhu et al., 1991b; Bakkali et al., 1994). There are numerous examples in which proteomics was used to discover new biomarkers while commercial tests are based on assays using different principles, e.g. ELISA (Sandhu et al., 1991a; Hampel et al., 2004).

49.4. Biomarkers

Biomarker in disease can be defined as quantifiable analyte(s) or factor(s) reflecting usually multiple changes in individual's physiological state. These changes, or better said, biological responses are at the molecular, cellular, or whole organism levels. They play critical role in assessing of disease outcome, in particular in patient treatment, and how these treatments will be individualized and/or modified in future clinical trials and how they will affect directions in drug development. Therefore, biomarkers must provide objective measures of normal versus pathogenic processes, responses to treatment whether it leads to a cure, improvement, or only maintenance of patient's health. Thus, biomarkers are absolutely essential for early diagnosis of any disease whether it is slowly progressing pathological process or acutely developing infection.

HIV-1-associated dementia (HAD) is a good example to discuss importance and qualities of good biomarker. HAD is a brain pathology developing in the late stage of HIV-1 infection and it is slowly progressing disease which once started ultimately leads to death. Currently, it is impossible to predict and measure the time of onset and progression of HAD, the two critical parameters determining course of treatment. The main reason of such situation is lack of appropriate biomarkers, which will inform us about mechanism of brain injury caused by mechanisms triggered by HIV-1 in the brain. What will be a good and reliable biomarker of HAD? We expect that whether biomarker is found in CSF or plasma sample of diseased people, it will give us also an insight into cellular mechanisms of an ongoing infection. This part of biomarker characteristics is also important for those who are designing new clinical trials or regimes of existing treatments. Entering clinical trial is based on vague measures, which might be influenced by subjective impact of examiner carries additional risk of inaccurate results. Thus the ideal biomarker should inform us as precisely as possible about the mechanism, status, and prediction of therapy and disease and help in designing of "individualized" therapy for the most effective result. In our example of HAD, an activation of mononuclear phagocytes recruited in high numbers due to ongoing inflammation will

lead to conclusions that up- or down regulated proteins originating from these cells due to HIV-1 infection might be good candidates for biomarkers. Such approach, however, should be considered with caution. Our recent findings (Ciborowski et al., 2004) showed that although HIV-1 downregulates MMP-9 expression in monocyte derived macrophages in *in vitro* studies, the net level of this protein in CSF of HAD individuals as well as its net proteolytic activity is increased due to recruitment of high numbers of these cells to the inflamed brain (Ghorpade et al., 2001).

It is important to note that effective and good biomarker can be a specific fragment of protein which is present in diseased state but not under normal conditions. Currently, existing biomarker of this type is A β_{42} fragment of α -amyloid protein in Alzheimer's Disease (AD) (Olsson et al., 2003).

49.5. Proteomics in Biomarker Discovery

There are four key components which are necessary for performing proteomic (global) type of experiments: (i) identification of differences generated within the system under various physiological conditions, (ii) fractionation of complex mixtures of proteins and other molecules, (iii) identification differentially expressed proteins and their interacting partners, and (iv) data analysis including statistical analysis, algorithms for database searches, and protein networks. The choice of methods, instrumentation, and experimental approaches, however, should be selected based on the questions which are asked and answers which are sought. A separate field of so called "hyphenated methods" is being developed and deals with combining two or more methods, first one is separation/fractionation of analyzed sample and the second one is in-line connected detection system. Hyphenated techniques were developed and were popular in 70s and 80s—more than 20 years ago and remain vital part of current technological advancement (Murray et al., 1975; Lee et al., 1976). An example of the most commonly used in proteomics is LC-MS (liquid chromatography combined with mass spectrometry) or in other global screening approaches are GC-MS (gas chromatography combined with mass spectrometry) (Kazakevich et al., 2005) and LC-UV-SPE-NMR (liquid chromatography, UV detection, solid phase extraction, and nuclear magnetic resonance) (Exarchou et al., 2006). Sample fractionation prior to detection and/or analysis usually leads to enhanced analytical outcome.

Hyphenated techniques (methods) are meeting a big challenge of proteomic analyses which is an extremely large and dynamic range of protein levels (Julka and Regnier, 2005; Kusnezow et al., 2006). Proteins in serum/plasma may range from 10 to 10¹² fold difference in abundance making it impossible to observe all proteins in one experiment (Jacobs et al., 2005). Therefore, fractionation of complex mixtures such as whole cell lysates into a reasonable number of samples becomes inevitable and new methods of enriching low abundance pro-

teins are required. Rapidly developing technology of protein arrays discussed in more details below is an attempt to address this issue. From a technical point of view, this technology leads to objective similar to genomic arrays: effective and sensitive protein analysis using automated instrumentation to perform a large number of parallel measurements. This also makes possible to screen functions such as protein-antibody, protein-protein, protein-ligand, protein-drug, and enzyme-substrate interactions, and perform multianalyte diagnostic assays.

A second major challenge for proteomics is transitioning from global analysis and profiling to focused studies on one or several proteins whose function(s) and/or interaction(s) are significant in biological processes and to further use of generated results for more focused screening and developing commercial diagnostic tests. Thus success of proteomic type of analysis is using data and information accumulated from all kind but most importantly from high throughput experiments, to address very specific questions of biological importance. These answers will determine how we will manipulate experimental conditions applied to the systems we study and to these parts of broad proteomics methods, which will be applied as a read-out of changes.

Proteomics cannot exist without interdisciplinary research, grouping experts from a wide variety of specialties, who understand and are able to communicate issues related to protein chemistry and to bring proteomics to a level of functional studies. Currently, research teams combining a relatively narrow group of scientists including protein chemists, mass spectrometrists, and bioinformaticians push the levels of sensitivity and accuracy of analytical instrumentation to unprecedented levels but experiments remain at the stage of cataloging proteins. One example of global proteomics analysis such as the HPPP (Omenn et al., 2005), can be accomplished only through international collaborations of laboratories equipped with various types of mass spectrometers and capable of performing complex analyses. Long term goals of this initiative are to perform comprehensive analysis of plasma and serum protein constituents in people, identify biological sources of variation within individuals over time, across populations and within populations including such factors as age, sex, menstrual cycle, exercise, with validation of biomarkers. Selected diseases, special cohorts, and common medications are also being discussed as parts of HPPP (for more information go to <http://www.hupo.org/research/hppp/>). Human Brain Proteome Project (HBPP) is even more ambitious in its goals. It includes defining and deciphering normal brain proteome, correlation of the expression pattern of brain proteins and mRNA, identification, validation, and functionally characterization disease-related proteins involved in neurodegenerative diseases and aging by differential protein expression profiling, and establishing a neuroproteomic database accessible to all participating laboratories and the scientific community, just to mention the few. More details can be found at <http://www.hupo.org/research/hbpp/>.

Undoubtedly, efforts of this and other currently ongoing international initiatives, will build a foundation for new discoveries and functional studies. Everyone in the broad research community will benefit from this work, particularly a rapidly growing number of smaller proteomics laboratories and programs with research goals focused on specific question(s) of biological importance. The most exciting future lies in functional studies combining proteomic and genomic approaches. However, to link results of genomic and proteomic studies will require innovative approaches because posttranslational modification making protein product biologically active may depend on distant genes and their products but on gene coding for polypeptide of this protein. New tools for profiling focused groups of modifying enzymes such as phosphatases or kinases are emerging and will be effectively used for better understanding of an impact of posttranslational modifications.

49.6. Proteomics of CSF

Total volume of CSF in adult human is about 130–150 ml and production rate is relatively constant under normal physiological conditions, approximately 0.4 ml/min (more than 500 ml daily). This means that turn over of CSF is at the rate of 4 volumes daily. The significant decrease in CSF secretion and turn over is associated with neurological diseases such as Alzheimer disease and chronic hydrocephalus (Tsunoda et al., 2002; Silverberg et al., 2004) reflecting physiological status of central nervous system (CNS).

CSF surrounds the brain and spinal cord and acts as an intermediate between blood and nervous tissues. Functions of the CSF include buoyancy, acid base buffering and delivery of electrolytes, signaling molecules, transport molecules and micronutrients to the brain parenchyma (Silverberg et al., 2004). CSF is produced predominantly by choroids plexus, specialized vascular tissue located in the brain ventricles (Serot et al., 2003). Choroid plexus tissues are intraventricular structures composed of villi covered by a single layer of ciliated, cuboid epithelium. The plexuses secrete CSF, synthesize numerous molecules, carry nutrients from the blood to CSF, reabsorb brain metabolism by-products and participate in brain immunosurveillance (Serot et al., 2003). Active transport across the choroid plexus is bidirectional so there is also macromolecular transport out of CSF. Blood flow to the choroid plexus is approximately six-times greater than that of the equal volume of brain tissue, suggesting that the choroid plexus is very metabolically active (Silverberg et al., 2004).

Changes in biochemical composition of CSF could serve as a useful tool for investigations of pathological processes in the CNS. CSF is also in contact with the blood plasma through the blood-brain barrier, thus resembling an ultrafiltrate of plasma in its protein constituents. CSF contains sugars, lipids, electrolytes and proteins. Protein concentration in CSF ranges from 0.2 mg/ml to 0.8 mg/ml (0.3 – 1% of serum protein concentration) with more than 70% of the proteins in CSF

being isoforms of albumin, transferrin and immunoglobulins (Ogata et al., 2005; Wittke et al., 2005). The proteome of CSF contains proteins that are expressed in, and secreted from circumventricular CNS structures. Therefore, the CSF proteome could provide unique biomarkers for early-stage diagnosis or the staging of a neuronal disease, offer potential insight into the biochemical characterization of affected neuronal population, and clarify the molecular basis of CNS pathologies (Yuan and Desiderio, 2003, 2005).

Previous studies have used proteome comparisons to study such neurological disorders as Alzheimer's disease (AD), Parkinson's disease (PD), frontotemporal dementia, schizophrenia, and Creutzfeldt-Jacob disease. Some examples of utilizing proteomics approaches for discovery of biomarkers for neurological disorders in human CSF are given in Table 49.2.

Investigation of biomarkers in CSF has some important limitations. Availability of larger volumes of CSF samples is limited by the need for invasive lumbar punctures. The large dynamic range of protein concentrations, which can be up to twelve orders of magnitude between the highest and the lowest expressed proteins, makes the analysis difficult (Maccarrone et al., 2004). Various schemes of sample pre-fractionation have been used to circumvent these problems. The widely used albumin removal method is affinity chromatography on Cibacron Blue resins (e.g. Cibacron Blue F3-A agarose); however, this method is not specific only to albumin and it is known to bind numerous other proteins (Gianazza and Arnaud, 1982; Maccarrone et al., 2004). Cibacron blue based depletion could be coupled with utilizing protein G resins to bind immunoglobulins from biological samples (BioRad, Hercules, CA). A newer approach is to use immunoaffinity methods utilizing monoclonal or polyclonal antibodies to deplete not only albumin, but also other highly abundant proteins from biological samples. Resins coupled with antibodies could be packed in HPLC columns for depletion most abundant proteins (e.g. Multiple Affinity Removal System, Agilent Technologies, Inc., Palo Alto, CA) for simultaneous depletion of 6 proteins.

Application of that column for CSF preparation before 2D electrophoresis and shotgun mass spectrometry was compared with Cibacron Blue and protein G resins by Maccarrone et al. (2004). Immunoaffinity column showed less nonspecific binding of CSF proteins. Another example of pretreatment CSF samples before proteomic analysis is using the IgY antibody microbeads and spin filters for depletion of most abundant proteins (Seppro Mixed 6, GenWay, San Diego, CA). Comparison of IgY microbeads and immunoaffinity column for pretreatment of CSF samples was performed by Ogata et al. (Ogata et al., 2005), the column format removed the major proteins more effectively and approximately 50% more spots were visualized when compared to the 2D gel of CSF without protein depletion. Two other commercially available kit for removing of HSA and HSA/ IgG were used by Ramstrom et al. (2005) for CSF preparation prior to Liquid Chromatography FT-ICR Mass Spectrometry (LC-FTICR MS). Both depletion methods provided a significant reduction of HSA, and the identification of lower abundant components was clearly facilitated.

Every method of removing high abundant proteins from CSF samples before proteomic analysis facilitates identification of discrete proteins, which could be important as a biomarker of physiological stage of CNS. However, the possibility of nonspecific removing of important peptides (through nonspecific binding to resins or forming complexes with target proteins) should be taken into account. Therefore, albumin fraction with co-purified proteins should not be discarded and should be analyzed in separate experiments. One-dimensional electrophoresis followed by mass spectrometric analysis can be applied for such analyses.

49.7. Neuroproteomics

Proteomic studies of the brain pose significant challenges. Brain tissue collection, dissection, preservation, biochemical and molecular integrity are all critical aspects of neuropro-

TABLE 49.2. Summary of protein biomarkers of neurodegenerative disorders discovered using proteomics approach.

Disease	Biomarker (protein)	Applied method	Lit.
Alzheimer's disease	Cystatin C, B-2 microglobulin isoforms, 4.8 kDa VGF polypeptide, unknown 7.7 kDa polypeptide	SELDI-TOF and LC/MS	(Carrette et al., 2003)
	Apolipoprotein A1, apolipoprotein E, apolipoprotein J, B-trace, retinol binding protein, kininogen, alpha-1 antitrypsin, cellcycle progression 8 protein, alpha 1B glycoprotein, alpha - 2 - HS glycoprotein	2D SDS-PAGE and MALDI-TOF	(Puchades et al., 2003)
Frontotemporal dementia	Transthyretin, fragment of VGF S-cysteinylylated transthyretin, truncated cystatin C, fragment of chromogranin B	SELDI-TOF and MS/MS	(Ruetschi et al., 2005)
Creutzfeldt-Jacob disease	14-3-3 protein cystatin C	2D SDS-PAGE, SELDI-TOF and LC-MS/MS	(Harrington et al., 1986; Sanchez et al., 2004)
Schizophrenia	Apolipoprotein A-IV	2D SDS-PAGE and LC/MS	(Jiang et al., 2003)
Multiple sclerosis	Cartilage acidic protein, tetranectin, SPARC-like protein, autotaxin t	2D SDS-PAGE and LC -MS/MS	(Hammack et al., 2004)

teomics and neurogenomics. Despite of the fact that many proteins and nucleic acids are stable postmortem (Yates et al., 1990) rapid degradation of other proteins may result in changes in overall protein composition (Abbott, 2003; Choudhary and Grant, 2004). Protein profile can change rapidly within minutes after death making very difficult to sort out changes related to disease from those related to death itself. In many studies done so far, protein extract of entire brain was used without distinguishing specific regions (Wang et al., 2005). To address these issues a variety of techniques of brain dissection have been developed (Sanna et al., 2005). Manual dissection methods are still very useful yielding enough material for microarray analysis with somewhat limited "contamination" of sample of interest with neighboring region which may affect reproducibility of genomic and proteomic analyses. Ultimately, laser dissection technique will be the method of choice for retrieving small, region(s), even single cell of interest, from brain tissue to improve anatomical accuracy (Evans et al., 2003). CSF obtained postmortem might be also valuable source of information, however, it has to be analyzed with caution because of brain necrosis following death (Lescuyer et al., 2004). Nevertheless, Lescuyer et al. found in postmortem collected CSF samples three proteins which have been reported as potential markers of various neurodegenerative disorders. These proteins are prostaglandin D synthase, glial fibrillary acidic protein, and cathepsin D. Other proteins include ubiquitin C-terminal hydrolase L1, peroxiredoxin 5 (Lescuyer et al., 2004).

While some neurological disorders such as AD, PD, HAD, Multiple Sclerosis (MS), or Amyotrophic Lateral Sclerosis (ALS) are slowly developing diseases, brain injury due to stroke, trauma, exposure to toxic substances, or hypoxia require immediate intervention. Nevertheless, in all these cases central nervous system is affected and to various extents damaged irreversibly. Thus fast diagnosis and medical intervention are absolutely critical for the outcome of acute diseases such as stroke and bacterial/viral meningitis. Slowly developing diseases such as AD, PD, HAD, MS at this time are diagnosed based on physiological tests, which are not very precise and do not provide precise evaluation of disease progression or treatment efficiency. In both scenarios there is a great need for new, reliable, and accurate biomarkers aiding in objective measurements of disease progression and treatment.

Proteomic and genomic technologies, and in particular when combined as functional genomics are new and promising experimental approaches in creating expression profiles of proteins and their connection with disease specific changes starting with transcription and ending at the level of posttranslational modifications and subcellular localization. Although this area of research is relatively new, it seems to be more convincing that molecular mechanisms underlying many neurodegenerative disorders may have common features. Aggregated and modified proteins (α -synuclein in PD and tau in AD), deregulation of mitochondrial functions leading to overproduction of toxic ROS, overproduction of glutamate

are factors responsible for neuronal death are observed in many neurodegenerative disorders (Sultana et al., 2006). Nevertheless, triggers of neurotoxic mechanisms are vastly unknown and various proteomic techniques are employed to address these questions. High-throughput shotgun analysis used by Soreghan et al. (2005) to identify targets of protein carbonylation in PS1 + APP transgenic mouse model pointed iNOS-integrin signaling, CRE/CBP transcription regulation, and rab-lyst vesicular trafficking pathways as future research directions on neurodegeneration.

Another neurodegenerative disorder ultimately leading to death is HAD. Despite of dramatic effect of antiretroviral therapy (ART) on slowing disease progression, HAD continues to be major cause of morbidity and death (Gendelman et al., 1998; McArthur et al., 2003) suggesting that ART does not provide complete protection against neurological damage in HIV-infected brains. Laboratory measures of HIV-1 associated inflammation of the brain, HIV Encephalitis (HIVE), or HAD progression developed so far, although valuable, are not diagnostic of HAD (Tornatore et al., 1991; Gendelman et al., 1998; Anderson et al., 2002). This new situation creates a demand for more accurate and reliable markers for monitoring HAD progression. Proteomic analyses of CSF samples obtained from HIV demented individuals is one approach taken by us and others. Another approach is based on the hypothesis that *in vitro* HIV-1 infected macrophage will secrete specific proteins which will be present in CSF samples of HAD patients. Combining both approaches should result in discovering new biomarkers. We also postulate that future diagnosis of HAD progression will be based on a set of multiple markers which levels will be measured based on background levels characteristic for individual being diagnosed and will be combined with psychological and brain imaging tests.

49.8. Functional Genomics

Genomics is the study of genes and their function. It is a broad definition of understanding the structure and molecular mechanisms underlying function of the genome. As the field of genomics is maturing, subfields emerge. Thus, functional genomics will incorporate protein products into gene characterization, structural genomics will include structural features of genes and chromosomes, comparative genomics will deal with evolutionary aspects of genomic organization and their interspecies relationship, epigenomics is focused on DNA methylation and pharmacogenomics will study targets for new drugs.

Genomics as a scientific field as well as a technology platform is much more advanced than proteomics. Availability of relatively fast sequencing of large sets of genes, in fact entire genomes, is today's reality and the major factor slowing our progress in this area lies in financial resources. Nevertheless, more genomes are sequenced expanding our knowledge which is not only focused on collecting and cataloging of data but mostly on studying how the genome functions.

Sequencing genome primates who are a link to the development of *Homo sapiens* is a challenging and intriguing task. If we can answer a question how our brains evolved and how different they are on the functional level from those of chimpanzees or maccacs, our ability to understand mental disorders would be greatly expanded. There is no doubt that two avenues of genomics, evolutionary and developmental, will be rapidly expanding in the next decade. However, the third avenue, which is our understanding of pathological processes resulting from inflammation and/or trauma (e.g. stroke injury), is much more complex and challenging. Recruitment of mononuclear phagocytes from the periphery and their responses beyond the blood brain barrier add another substantial level of complexity. Do these cells constitute part of the brain or do they switch from bystanders to a role of active players? One of limitations in neurogenomics is the lack of good models to study variety of aspects of brain function. For example, a stimulus leading to change in reaction, e.g. from friendly to aggressive can be quite different between humans and rodents which are very often used in such studies. Another important question is whether these changes occur at the genome level or maybe downstream at the level of activation of certain enzymes without much change in the levels of expression.

49.9. Gene Arrays

In genomic studies microarray technology is used for the rapid quantitative measurement of gene expression in a tissue. mRNA which is directly transcribed from DNA template not only reflects levels of gene expression but also is used directly for hybridization on DNA chip. Levels of complementary hybridization are measured by laser scanning of fluorescently labeled RNA molecules bound to the chips and data are further subjected to computational processing for quality control (sources of errors) and detection of altered gene expression. Multiple experiments can be performed using this experimental approach in which data are combined, normalized, and analyzed for elucidation of distinct pattern characteristic for the studied system. Implementation of chips in microarray assays led to real multiplexing increasing throughput and speed of experimental progress. Miniaturization, improved manufacturing with better quality and affordability make microarray technology widely available. Group effort of technological advancement of more than twenty companies and numerous academic and other laboratories resulted in high density chips becoming available. For example, Affymetrix chips contain 400,000 groups of nucleotides in an area of $\sim 1.6\text{cm}^2$. Chips with wide range of genes, focused microarrays narrowed to specific groups of genes as well custom made products make this technology platform suitable for addressing questions of biological importance, for clinical diagnostics and in biomarker discovery. Therefore, microarray technology has broad applications in such areas as expression profiling, func-

tional genomics, pharmacogenomics (Meschia, 2004), and developmental (Jensen et al., 2004) and evolutionary biology (Sikela, 2006).

Despite the fundamental importance of genomic experiments, this technology platform provides only initial and far from completion results. Proteomics, on the other hand, is a follow-up approach, and when results acquired from both technology platforms are combined, more comprehensive picture of functional significance arises. Integration of these two experimental platforms is another challenge because of complexity of systems biology. *First*, a bottom-up or a top-down strategy has to be chosen for experimental strategy. *Second*, which part will be a driving force, genomics or proteomics? *Third*, an integrated bioinformatics platform has to be secured for complementary and coherent transformation of data into information. A possibility to produce custom made DNA microarrays designed and manufactured by commercial entities and/or individual investigators to address specific biological question(s) provide enormous support to such integrated strategies. Extensive literature can be found reviewing technical issues related to gene arrays including hybridization, post-hybridization quality control, normalization and data processing, (Boes and Neuhauser, 2005; Hartmann, 2005; Reimers, 2005). These specific tools allow performing genomic experiments based on results generated in initial proteomic studies. Our experience with such studies, show that experimental design and depth of data mining are critical.

49.10. Genomics in Neuroinflammation

Along with increasing human life expectancy, it is believed that in the next 50 years neurological disorders will exceed as a human health problem such diseases as cancer or heart diseases. Neurological disorders associated with age, e.g., AD, PD, ALS, and other diseases such as HIV-1-associated cognitive impairment are correlated with inflammatory response of innate immunity system in the CNS. Response to insult such as bacterial or viral infection, stroke, cancer metastasis, or abnormal expression and accumulation of self proteins is associated not only with activation of resident macrophages, but is also associated with recruitment of large pool of mononuclear phagocytes (MP) from the periphery. These cells migrate through blood brain barrier to clear the insult and protect brain from further damage. In reality, the phenotype of MPs can produce neurotoxic outcome at the site of injury. The traditional approach to study human diseases has been to focus research projects on the study of important pathogenic factors: relevant microorganisms (Qureshi et al., 1999) and other agents linked to pathogenesis such as β -amyloid in AD or α -synuclein in PD with hope for development of effective treatment. This approach limited our progress in understanding of molecular basis of host defense mechanisms. Therefore, understanding what precisely regulates macrophage responses

in the brain and how they interact with other types of cells is critical for more effective therapies (Ciborowski and Gendelman, 2006; Foti et al., 2006). New experimental approaches such as gene microarrays now can be used to overcome previous limitations of experimental manipulation and large sets of data, and facilitate genomewide analyses.

Genomics is one approach that can discover new clues leading to better understanding of MPs' function. Under normal conditions, monocytes derived from bone marrow circulate in the blood for approximately 48 h and migrate to tissues where they differentiate into macrophages. Differentiation will be driven by local tissue environment and is not completely reversible when macrophages are removed from various tissues and grown *in vitro* under the same conditions (Enose et al., 2005). Nevertheless, principal functions of these cells – clearance of debris, antigen presentation, phagocytosis, production reactive oxygen and nitrogen species to fight infection will remain the same regardless of tissue localization. Therefore, design of experimental conditions to study MPs' responses will play a critical role in data interpretation and in drawing conclusions. We may expect that genomic studies of, e.g., alveolar macrophages exposed to tobacco smoke (Wu et al., 2005), macrophage from cells generated *in vitro* by treatment of monocyte-derived macrophages (MDM) with oxidized low-density lipoprotein (LDL) (van Duin et al., 2003), or MDM exposed to aggregated α -synuclein will lead to understanding critical similarities and differences underlying inflammatory immune responses. Such comparative genomic studies (Heller et al., 1997) will produce vast amount of data critical for understanding neuroinflammation, which suffers from the lack of a good animal model.

The genomic approach has proven to be indispensable as an initial step in determining any given function. After all genes are coding proteins. On the other hand, the role of gene is finished as soon as transcription is completed. In the following steps, transcripts undergo a complex process leading to functional protein, a product that eventually performs a task. But we have to keep in mind that if an error occurs at transcription level and is reproduced over and over again, a faulty final product is made regardless how good and precise downstream machinery is. Brain is an organ from which biopsies are taken under very specific circumstances, e.g., brain tumors. Such material is further examined for histopathological evaluations. In future, this now well-accepted method will be combined with genomic, proteomic, and metabolomic signatures of tumor cells (Petrik et al., 2006).

Another obstacle in studying brain functions is our limited ability to purify specific populations of cells from either animals or postmortem from human brains. This limitation concerns both proteomics and genomics in a very similar way. Many brain cells such as neurons are terminally differentiated and do not proliferate. On the other hand astrocytes can be grown *in vitro*, therefore, neurons are always "contaminated" with other types of cells (Zheng et al., 1999, 2001). Ability to amplify mRNA in a preparation obtained from cell culture or

cell preparation may lead to false conclusions. In situ hybridization can be used for verification; however, this method is laborious and cannot be used in a high throughput analyses.

49.11. Protein Microarrays

Over the last two decades DNA microarrays showed applicability of high throughput studies of gene expression and regulation under various experimental conditions (DeRisi et al., 1996; Khan et al., 1999). Therefore, the idea of developing similar technique for easy analysis of multiple protein samples in parallel was very attractive (Haab et al., 2001). Advancing miniaturization quickly translated to smaller samples required for analysis along with decreasing costs of spotted membranes boosted the demand. Early approach utilized phage displayed of relatively short sequences of amino acids for probing complex mixtures of proteins and screening their binding capacities (Scott and Smith, 1990; Smith and Scott, 1993). Protein microarrays based on antigen-antibody interaction meet such criteria and it obvious that this technology is rapidly filling a gap between genomics and proteomics. The ability of protein quantitation makes this approach even more attractive. Recent years brought a rapid development of various forms of protein microarrays (Templin et al., 2003; Poetz et al., 2005). Limitation of protein microarrays lies in requirement of highly specific capture and detection antibodies or other interacting molecules. Although in DNA microarrays this pre-requisite was accomplished due to high selectivity of hybridization of complementary sequences, they still suffer from some percentage of ambiguous results. In proteomics, posttranslational modifications add another level of molecular diversity and complexity. For example, many proteins, although different, share common modifications such as phosphorylated tyrosines. In these cases it is necessary to identify location of phosphorylated residue on the protein of interest.

Protein microarrays is a powerful tool when proteomic analysis is narrowed to a group of proteins such as growth factors, chemokines, cytokines etc. These classes of proteins already have a great number of pre-required well-characterized and highly specific antibodies reacting with high affinity. Such protein arrays (chips) were immediately developed and are successfully used in monitoring markers of immune responses (Kastenbauer et al., 2005) complementing DNA arrays (Ho et al., 2005). Ho et al. showed that complementation of cDNA and protein arrays in search of biomarkers of Alzheimer's disease can be consistent. Similarly to ELISA system, quality of protein microarrays will depend on the background signal from nonspecific adsorption of labeled protein increasing along with protein concentration. Detection limit of protein of interest will be determined not only by its absolute level in tested sample, but also by the high levels of other proteins with ability to cross-react in a nonspecific manner. Levels of detergents and other components of lysis buffers used prior to analysis have to be taken into account. The latter issue is of

critical importance when sample needs to be concentrated and analyzed by MALDI type of mass spectrometer.

Accuracy and reproducibility of protein array data further depends on proper experimental design, normalization procedures, eliminating systematic bias, and appropriate statistical analysis. Eckel-Passow and co-authors made several excellent suggestions how experiments should be designed and analyzed to avoid false results (Eckel-Passow et al., 2005). For example the authors propose to use several different clustering tools instead of single cluster analysis for verification of results in discovering differences in a class of molecules, e.g. cytokines. Another obstacle in working with protein microarrays is stability of protein structure which is critical for proper folding thus interaction with binding partner. Another side of this problem is exposure of interacting surface/epitope while immobilized on the chip. Protein microarrays suffered from skepticism and criticism during early stages of development. Nevertheless, this technology is gaining ground in biomedical research with increasing potential of application in clinical diagnosis. Similarly to DNA microarrays, one can find commercially available protein arrays specific for various microorganisms and diseases, user friendly kits with improved and sophisticated fluorescent tags. For those working in the area of drug developments, protein microarrays are vehicles of accelerated discoveries. For others, protein microarrays are envisioned as tools for exploration and understanding pathological processes, kinetics of changes on molecular level, interactions with molecules different in nature such as lipids, nucleic acids, carbohydrates, drug candidates etc.

49.12. Proteomics and Tissue Profiling

Can tissue be examined for a global protein expression directly and without time consuming sample preparation? Can such profiling be used effectively in a rapid clinical diagnostics to aid pathologists in their work? Can section of tissue be placed on target, covered with matrix and profiled directly in mass spectrometers? If this appealing but challenging idea becomes real, it would be a breakthrough in modern clinical diagnosis.

Early attempts to develop patterns of specific compounds and proteins were based on tissue homogenates (Burns, 1982; Jimenez et al., 1997; Mitchell et al., 1997). Tissue profiling, or more accurately called tissue imaging, based on direct mass spectrometry measurements is a much younger area of research which started being developed in late 90s when MALDI-TOF-MS measurements were performed on intact tissue sections (Chaurand et al., 1999).

MALDI-TOF types of mass spectrometers with high resolution and sensitivity reaching attomolar range is a class of instrumentation of choice for direct tissue analyses. Spectra are generated very fast, a wide range of mass is acquired. Hundreds and even thousands of spots can be analyzed using one tissue section which further processed by computers will create an image. Besides the high throughput of this type of

analysis, a major advantage is that collected spectra can be assigned to the localization on the tissue section, thus can localize molecules in question to tissue structures. This, in turn, is important for monitoring such processes as distribution of therapeutics, which can be small molecules as well as peptides and/or proteins. Questions that remain to be addressed in tissue imaging are whether and how important structural analysis (peptide sequence, drug structure) of identified species since downstream processing of spectra is based on the presence, intensity, and signal-to-noise ratio data. Scattered presence of another molecule(s) with close m/z (mass-to-charge ratio) can lead to misleading results. If the analyte's m/z is within 2000, identification based on sequencing can be performed in instruments equipped with post-source decay mode (Stoeckli et al., 2002). Another question is absolute quantitation, which is the weakness of MALDI-TOF comparing to other types of mass spectrometers. Nevertheless, meaningful information can be acquired if the system is properly validated. Validation of proteins can be accomplished using other methods, e.g., fluorescence immunochemistry and co-registartion. It is more challenging to quantitate small molecules (pharmaceuticals) by mass spectrometry without some kind of sample processing. Therefore, proper methods of validation need to be developed. Despite challenges discussed above, application of this technology is advancing resulting in reports such as classification of tumor samples using this technology platform (Chaurand et al., 1999) or single cell analysis (Li et al., 1999).

49.13. Bioinformatics and Information Networks

Expression of proteins and genes on a global scale requires new and efficient tools for database searches and data analysis. Such tools are advanced in genomics because this area of global analysis is much more advanced, while analysis of proteomic data is still in its early development. Algorithms used for proteomic database searching are being constantly improved. Currently, the mostly used algorithms for mass spectrometric peptide sequencing are MASCOT and SEQUEST. Recently published report from the pilot phase of HPPP experiment compares results from MS/MS spectra analysis using not only MASCOT and SEQUEST but also Spectrum Mill, and X!Tandem concluded that no one of these algorithms outperforms other and much improvement is needed in this area. New approaches were also applied such as processing very large numbers of raw spectra to generate clusters of spectra followed by SEQUEST-like analysis.

An important issue that arouse during early development of proteomic technology is proper comparison of data generated by different centers, laboratories, even individuals. SELDI-TOF is an example of how difficult it was to cross-validate data from laboratory to laboratory which used the same technology

platform and instrumentation. Mass spectrometry data can be very susceptible to errors originated from sample processing (Baggerly et al., 2004). The same applies to algorithms used for database searches and accuracy of protein identification based on mass spectrometric sequencing of peptides.

Summary

Proteomics is maturing from its early stages of fascination with ability of high numbers of protein identifications in a single experiment. Quantitative mass spectrometry of proteins is becoming standard method in proteomics laboratories. 2D SDS-PAGE supported by sophisticated software and increasing computer power along with more user friendly supplies providing better reproducibility is another technology advancing global protein outlook. Further technological developments of, i.e. tissue profiling by mass spectrometry and protein arrays, will facilitate a more precise view of changes occurring in proteomes resulting from alterations in biological system. New technology platforms and tools emerging almost every day will overcome current problems and limitations of proteomics such as sample processing, sample availability, reproducibility, quantitation, validation etc. We expect that significant biological advances: biomarker and drug discovery, disease and treatment monitoring, will be made during the coming decade.

This will be very important for understanding mechanisms leading to neurodegeneration such as HAD, AD, PD, ALS, and others. Another big step will be to go beyond slowing down or completely stopping the neurodegenerative process, and pushing immune system to repair the damage and promote regeneration. How much is it possible and how soon it can be accomplished remains an open question. It is without question, however, that understanding functions of complex biological systems such as duality of neurotoxic/neurotrophic functions of MPs in the brain during inflammation will require coordinated monitoring of large number of parameters at the same time and well-designed proteomics, genomics, transcriptomics, metabolomics, as well as neuro-imaging experiments.

Review Questions/Problems

1. What is proteomics?
2. What is genomics?
3. How does studying the proteome compare to studying the genome?
4. Review the challenges in proteomics research?
5. What is the difference between biomarker and risk marker?
6. Explain in which cases SELDI-TOF technology will be more advantageous than LC-MS/MS and/or MALDI-TOF.
7. What are the approaches used in the development of clinical proteomics?
8. Advantages and disadvantages in using protein arrays.
9. What are biomarkers and how are they identified and validated for use in the clinical setting?
10. Describe strategies of sample prefractionation for genomic and proteomic analysis.
11. Mathematical models of the molecular pathways in cells will facilitate:
 - a. prediction of previously unknown interactions
 - b. combining genomic and proteomic data
 - c. discover novel proteins, cellular functions, and pathways
 - d. all of the above
12. Successful translation of results from laboratory to clinic depends on:
 - a. exploratory research studies
 - b. validation
 - c. prospective screening studies on large-scale population
 - d. all of the above
13. Weakness of 2-dimensional SDS-PAGE is:
 - a. lack of superior reproducibility
 - b. lack of protection of proteins from structural destabilization
 - c. inability of obtaining protein sequencing data
 - d. lack of superior methods of protein labeling
14. Major difficulty in proteomic studies of certain type of samples such as CSF:
 - a. contamination with drugs penetrating through blood brain barrier
 - b. size and availability of the sample
 - c. lack of correlation with clinical diagnosis
 - d. contamination with red blood cells during spinal tap
15. Top-down approach in studies of systems biology is preferential over bottom-up approach because:
 - a. it provides more global view
 - b. it allows for faster conclusions which will lead to direct development of clinical tests
 - c. requires less sophisticated technology and instrumentation
 - d. both approaches are equal

16. Major question to be addressed when considering application of genomics and proteomics to screening and testing include selection of:

- mouse species
- non-radioactive reagents
- reputable provider of proteomics and genomics technologies
- conditions which are true reflections of *in vivo* biological function

17. Commercially available antibody arrays technology has many of the same problems observed with genomics because of problems associated with:

- data analysis, interpretation, storage, and retrieval
- high background created by not well developed reagents
- necessity of using radioactive materials
- inaccuracy of chips readers

18. The best approach to determine the sensitivity and specificity of these methodologies, and to validate and standardize these technologies?

- to reduce “biological noise” in the samples and reduce number of replicates
- to link data obtained from database searches to biological effects via fast computers
- to develop a standard approach to understanding and communicating variability in experimental data
- none of the above

19. While planning proteomics experiments, a researcher should:

- have available all types of mass spectrometers
- mandatory access to protein microarrays
- be aware of strength and weaknesses of each technology
- always be an expert in statistics and computer programming for solving problems associated with bioinformatics

20. Neuroproteomics analysis is most conclusive when

- experiments are done using entire brain so that all cell types are used in one assay
- only *in vitro* models are conclusive
- selected types of cell from a brain are obtained and manipulated
- two or more cell types are mixed together to facilitate interaction mimicking *in vivo* situation

Neuroimaging

Michael D. Boska and Matthew L. White

Keywords Magnetic resonance imaging; Magnetic resonance spectroscopy; Neurodegeneration; Positron emission tomography; Single photon emission computed tomography

50.1. Introduction

A wide range of neuroimaging techniques have been developed which aid in clinical diagnosis of neurological diseases and are valuable tools for research into basic physiological mechanisms and effects of new therapies to combat neurological disease. This is a rapidly evolving field as new imaging techniques with enhanced sensitivity and specificity are constantly being developed and made available to the clinician and research community. This chapter will provide an introduction to the basic mechanisms, capabilities and applications of neuroimaging methods, allowing the neuroscience student to gain an appreciation of the range of available imaging techniques and the potential for use as serial non-invasive monitors of the progression and treatment of neurodegenerative disease in animals and humans.

Neuroimaging techniques include nuclear medicine studies such as positron emission tomography (PET) and single photon emission computed tomography (SPECT). Morphological imaging methods include magnetic resonance imaging (MRI) and computed tomography (CT). Studies of brain physiology and biochemistry include PET, SPECT, CT perfusion, MRI perfusion, magnetization transfer MRI (to assess myelin loss), ^1H and ^{31}P magnetic resonance spectroscopy (MRS) and magnetic resonance spectroscopic imaging (MRSI). These methods provide a broad array of techniques for serial non-invasive measurement of alterations in brain physiology and biochemistry, which are early and sensitive indicators of many neurological diseases. Although structural imaging techniques are not always sensitive indicators of neurological disease, functional and molecular imaging methods, including SPECT, PET and physiological MR techniques, have great value as they can reveal abnormalities before structural atrophy or focal CNS lesions are visible.

Neuroimaging techniques can be broadly classified by the information content of the images. Morphological information can be obtained from MRI and CT, sensitivity and specificity

of MRI for detecting brain lesions is improved over CT (Brugieres et al., 1995) due to improved soft tissue contrast of MRI (Ell et al., 1987; Kim et al., 1996). In addition, MRI or CT can be combined with nuclear medicine techniques to provide anatomical detail allowing clear identification of the location of radioactive probes. Physiological information, including tissue perfusion mapping, mapping of receptor densities, and mapping of tissue biochemistry can be accomplished using MRI, MRSI, SPECT, and PET. Functional information, mapping of neuronal activity, can be obtained using functional MRI and PET, as well as other imaging modalities not covered in this chapter including electroencephalography (EEG), which records the electrical activity of the brain and magnetoencephalography (MEG) which provides spatially resolved maps of the electrical activity of the brain. This chapter will cover the basics of signal generation, signal acquisition and some examples of the information obtained in MRI, MRSI, SPECT and PET as an introduction to this broad and fascinating field.

50.2. Principles of Imaging

50.2.1. Basic Principles of MRI

MRI methodology is a complex and intriguing field of study. In this chapter, the basic mechanisms of MRI signal production and acquisition are introduced to allow the student of the neurosciences to develop a base understanding. Excellent textbooks are available for more advanced study of the details (Slichter, 1996; Haacke et al., 1999; Liang and Lauterbur, 2000; Gillard et al., 2005).

50.2.1.1. Signal Source

The signal in magnetic resonance imaging (MRI) and spectroscopy (MRS) rely on the magnetic properties of nuclei (Baier-Bitterlich et al., 1998). Nuclei with a non-zero *spin quantum number* ($I \neq 0$) will possess a *magnetic moment vector* μ . The magnetic moments are a result of the paramagnetic fields produced by the interaction of charged particles within the nucleus. The spin quantum number of the nucleus will be zero ($I = 0$) if both the mass number and the atomic number

FIGURE 50.1. The precession of the nuclear magnetic moment vectors μ about the static magnetic field vector B_0 . The angle of the precessional cone is given by θ . The precessional frequency is given by the Larmor frequency ω .

of the nucleus are even. These nuclei will not have a nuclear magnetic moment and hence are not observable using magnetic resonance techniques. Any nucleus with an odd atomic number or and odd mass number will have a non-zero spin quantum number ($I \neq 0$). These nuclei will have a nuclear magnetic moment and thus can produce a signal.

For nuclei with $I = 1/2$, including ^1H observed in MRI, the magnetic moment vector μ of the nuclei will either be parallel or anti-parallel to the externally applied magnetic field (Figure 50.1). The magnetic moment of a nucleus can be related to its angular momentum by the magnetogyric ratio of that nucleus defined by (Harris, 1983; Krane, 1987):

$$\gamma = \frac{\mu}{I} \quad (1)$$

where μ is the nuclear magnetic moment vector of a nuclear isotope, and I is the angular momentum (spin) quantum number of a nucleus. The magnetogyric ratio is constant for each nuclear isotope. The sum of all magnetic moments is the macroscopic magnetic moment, named the *Net Magnetization Vector M*, which is defined as:

$$M = \sum (\mu_+ + \mu_-) \quad (2)$$

where μ_+ and μ_- represent magnetic moments in the parallel and anti-parallel state for a two quantum states ($m_I = \pm 1/2$) of a spin $1/2$ magnetic nucleus ($I = 1/2$) such as the proton.

50.2.1.2. Precession and the Larmor Equation

The two states of different energy are not exactly parallel and anti-parallel to the external magnetic field. The magnetic moments are at an angle θ relative to the magnetic field due to the quantized energy states of the subatomic particles. The force of the magnetic field B_0 on the magnetic moments μ forces these nuclear magnetic moments into a precessional motion (Figure 50.1). The frequency of precession, also called *Larmor frequency*, is proportional to the magnetic field according to the Larmor equation:

$$\omega = \gamma \times B_0 \quad (3)$$

where ω is the rotational frequency of the net magnetization produced by excitation of the nuclear magnetic moments (rad/s), and γ is the gyromagnetic ratio, constant for a given nucleus. B_0 is the magnetic field strength at the nucleus measured in Tesla (T) or Gauss (G). $1 \text{ T} = 10,000 \text{ G}$. As an example, the resonance frequency of protons is 64 MHz at 1.5 T.

The net magnetization vector M is the source of MR signal. The time evolution of the net magnetization vector M is the signal source in magnetic resonance. Motion of M will create an oscillating magnetic field. This oscillating magnetic field will create an induced voltage in a receiving coil. This induced voltage in the receiving coil over time is the signal.

50.2.1.3. Resonance

When a nucleus is exposed to a secondary magnetic field (B_1) that has an oscillation identical in frequency and direction to its own Larmor precession, the nuclei absorb energy from the external source. The secondary magnetization is applied at the Larmor frequency, which is typically in the radiofrequency (RF) range, thus the brief application of the B_1 field is referred to as an RF pulse. Absorption of energy from the RF pulse results in a phase coherence in individual nuclei during the process of changing from the low energy to the high energy state. The net effect of B_1 is a tipping of M_0 (net equilibrium magnetization) away from the Z (longitudinal) axis (parallel to B_0) towards the X,Y (transverse) plane. The force of B_0 on the transverse component of M now rotates M_{xy} at the Larmor frequency. The rotating magnetization causes a voltage in a coil “tuned” to the Larmor frequency to pick up the signal by magnetic induction (Figure 50.2). The resulting angle between the Z axis and M (typically 90°) is called *flip angle* and depends upon the amplitude and duration of the RF pulse.

50.2.1.4. Signal Detection and Time Evolution

Faraday’s law of induction states that if a receiver coil is magnetically coupled to an oscillating magnetic field, a voltage is induced in the receiver coil. Therefore, as M precesses at the Larmor frequency in the transverse plane, a voltage is induced in the coil. This voltage constitutes the *MR signal*. The magnitude of the signal depends on the magnitude of M in the transverse plane. The amount of magnetization in the longitudinal plane gradually increases (T_1 relaxation). At the same time, but independently, the net magnetization in the transverse plane gradually decreases due to loss of phase coherence (T_2 relaxation). As the magnitude of transverse magnetization decreases, so does the magnitude of the voltage induced in the receiver coil (Figure 50.2). The evolution and decay of the net magnetization, M is picked up by the receiver coil resulting in the magnetic resonance signal, the *free induction decay (FID)*.

FIGURE 50.2. Application of a secondary magnetic field (B_1) rotating at the Larmor frequency has the effect of tipping the net magnetization (M) away from the equilibrium position (M_0) along the longitudinal axis and towards the transverse plane. After the brief application of B_1 , rotation of M in the transverse (X - Y) plane at the Larmor frequency (B) induces a Free Induction Decay (FID) signal in a pickup coil (C).

When the RF pulse is switched off, M realigns with the Z axis at a rate ($1/T_1$) slower than the rate of signal loss ($1/T_2$). In order to do so, M must transfer the energy gained to the surrounding molecules. This process is referred to as T_1 relaxation (spin-lattice relaxation). As T_1 relaxation occurs, M returns to equilibrium (M_0).

50.2.1.5. Magnetic Field Gradient Used to Generate MRI

The magnetic field dependence of the signal's frequency is used as a basis for spatial encoding of the magnetic resonance signal. This is done using magnetic field gradients. Magnetic field gradients cause a linear shift in magnetic field with position. This allows one to use a single chemical species, such as water, as a signal source for imaging (MRI). Sophisticated spatial encoding schemes have been developed to allow multi dimensional spatial encoding.

The Larmor equation demonstrates the basis of these encoding schemes. As the magnetic field changes, so does the frequency. In one dimension, application of a magnetic field gradient of 10 gauss/cm [1 Tesla (T) = 10,000 gauss (g)] produces a field shift in the water frequency of 64 MHz (1.5 T) of 42667 Hz/cm. The basis of the use of the magnetic field gradient for spatial encoding is displayed in Figure 50.3.

50.2.1.6. Fourier Transform: Frequency Analysis of the Time Domain MR Signal

The time domain MR signal is difficult to visually interpret; hence, the signal is transformed into a spectrum, which is intensity

on the vertical axis and frequency on the horizontal axis. This is performed mathematically by the Fourier transform. The Fourier transform is performed according to the equation:

$$f(\omega) = \int_{-\infty}^{\infty} f(t) e^{-i\omega t} dt \quad (4)$$

where ω = frequency (radians/s), t = time (s), $i = \sqrt{-1}$, $f(\omega)$ is the frequency domain signal (spectrum) and $f(t)$ is the time domain signal (MR signal, free induction decay or spin echo).

50.2.1.7. Spin Echo

Signal loss in the free induction decay (FID) can be partially refocused using a second application of B_1 with a duration and amplitude that produces an 180° flip angle of M (180° pulse). This has the effect of placing individual magnetic moments, which are no longer in phase with the central frequency, in a position to realign with spins at the central frequency.

Pulsed magnetic resonance experiments are represented by parallel time lines of the applied pulses and the signal (Figure 50.4A). We will introduce this formalism here to explain the spin-echo and, in the next section, the spin-echo MRI pulse sequence. The first line is the time line of the applied B_1 pulses, also referred to as radiofrequency, or RF pulses because they are applied at the Larmor frequency, which are typically in the radiofrequency range.

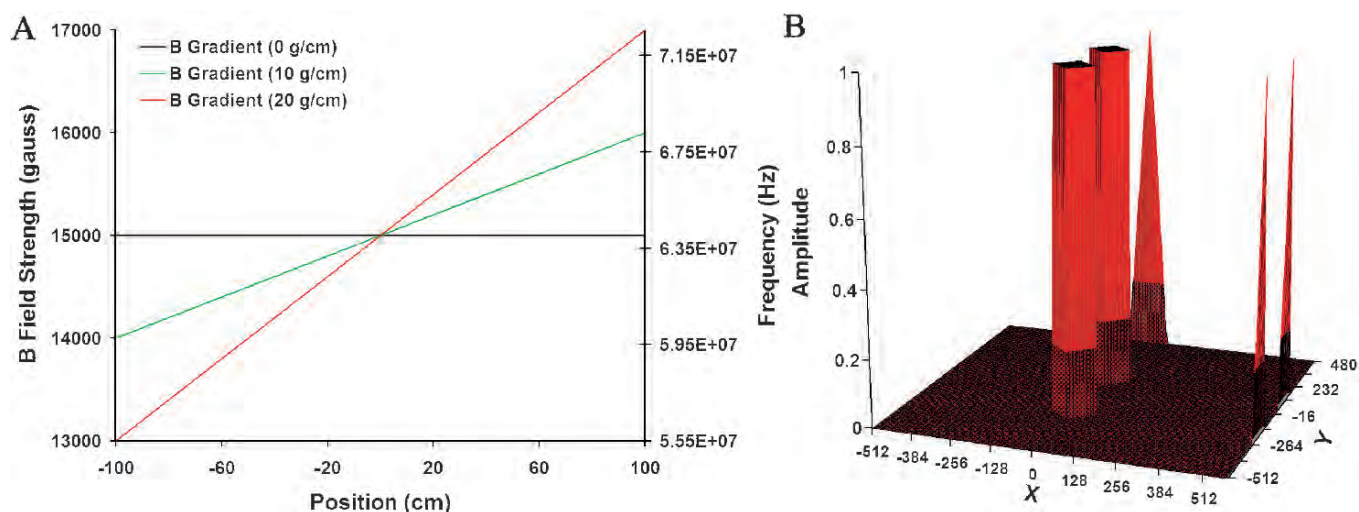

FIGURE 50.3. Magnetic field gradients used for frequency encoding spatial position. A: Magnetic field strength as a function of position in the magnet for three gradient strengths. B: Arbitrary object within the MRI system (center) and the frequency readout (signal) from a gradient applied during signal acquisition along the x-axis (rear) and the y-axis (right).

FIGURE 50.4. Time evolution of the spin-echo signal. A: Pulse sequence diagram showing (top) the timing of the applied 90 and 180° RF pulses (B_1) and (bottom) the time evolution of the spin-echo signal. B: Vector diagram of the time evolution of the spin-echo signal. Clockwise from top-left: Equilibrium magnetization is rotated by the 90° RF pulse, signal evolves and individual spins lose phase coherence, reducing signal intensity, a 180° RF pulse is applied which places out of phase magnetic moments in position to rephase at a time (τ) equal to the time of dephasing before the 180° pulse, allowing the refocusing of the signal (spin-echo).

50.2.1.8. Spin-Echo Magnetic Resonance Imaging (MRI)

Three dimensions of spatial encoding are required for MRI. These three dimensions are independently applied by (1) signal production from a thin slice by using a frequency selective excitation in the presence of a magnetic field gradient (slice selection), (2) acquiring the spin-echo signal in the presence of a magnetic field gradient (frequency or read-out gradient) and acquiring the spin-echo signal after producing a spatially dependent phase shift which is incremented in the second dimension (phase encoding gradient). The pulse sequence diagram showing the application of the frequency selective RF pulses, the slice, phase and frequency encoding gradients and the spin-echo signal acquired are shown in Figure 50.5. The spin-echo acquisition is repeated for each value of phase encoding gradients to fill in the second dimension of the single slice MRI, requiring repetition of the sequence 256 times for 256×256 image resolution. The raw MRI is acquired in the time domain, which requires Fourier transform of the signal into the frequency domain for display (Figure 50.6).

50.2.2. Modification of Signal Intensity

The power and versatility of magnetic resonance techniques lie in the ability to modify signal intensity based on the biophysical properties of the spins of interest (primarily tissue water). Signals can be “weighted” (signal amplitude altered) based on the magnetic relaxation properties (T_1 and T_2), water diffusion (random molecular motion), or the interaction of the hydration layers of membranes and proteins with free water (magnetization transfer). Tissue perfusion can be mapped by the introduction of contrast agents or inversion of signal from water in arterial blood supply of the tissue. In addition, signal can be suppressed from tissue based on frequency (fat

or water suppression), position (suppressing motion artifacts from unwanted tissue), or preferentially viewed based on moving vs static water (angiography or suppression of signal from flowing blood).

50.2.2.1. Magnetic Relaxation, T_1 and T_2

50.2.2.1.1. Spin-Lattice Relaxation (T_1)

T_1 relaxation is the process of releasing the energy absorbed by the magnetic nuclei during the application of the RF pulse. This process occurs by releasing the energy to the surrounding molecules (lattice) returning the spin system to the equilibrium condition (M_0). The rate at which this process occurs in tissue depends on the molecular environment and varies with tissue type, providing a means of generating contrast between tissues with otherwise similar signal intensities (water content). T_1 relaxation occurs exponentially after an RF pulse with a time constant of T_1 according to the equation:

$$M_z(t) = M_0(1 - e^{-t/T_1}) \quad (5)$$

where: $M_z(t)$ is the time dependent amplitude of the Z component of the magnetization (along B_0), which approaches the equilibrium magnetization (M_0) over time (t) with the time constant T_1 . Since MRI acquisition typically requires multiple

excitations, adjusting the repetition time (TR) between successive excitations reduces the net magnetization according to TR/T_1 and alters the T_1 based contrast. As a result, signal intensity within each volume element in the MR image (voxel) has intensity modified by the average T_1 of tissue within the voxel according to the repetition time of the acquired image. This occurs as illustrated in Figure 50.7A. Figure 50.7A shows the Z-magnetization recovery curves for two different tissues, one with a T_1 of 400ms and one with a T_1 of 900ms. In order to recover full magnetization, a delay (TR) of $5 \times T_1$ is required. Using a short TR (500ms, dashed lines) the tissue with the 400ms T_1 has recovered to 71% of M_0 while the tissue with the 900ms T_1 has only recovered to 43% of M_0 . The signal intensity will be proportional to the recovery of the net magnetization after the second 90° RF pulse, providing a signal that is 65% more intense for the shorter T_1 tissue even if the original signal intensity (M_0 , proportional to water content) is identical, providing improved tissue contrast and a mechanism for detecting altered cell content (pathology) within tissue.

50.2.2.1.2. Spin-Spin Relaxation (T_2)

The spin echo (Section 50.2.1.6) demonstrates that the 180° RF refocusing pulse reverses off-resonance effects (spins at a slightly different frequency than the Larmor frequency) after the 90° RF pulse allowing a signal to be generated at a time after the original signal loss. However, the natural process of energy exchange between adjacent molecules causes a loss of signal coherence by exchange of spin states with loss of phase coherence. This loss of signal cannot be refocused. The exchange of spin states with no net loss of energy in the spin system is referred to as spin-spin relaxation (T_2). Signal loss as a function of echo time (or TE) is given by:

$$M = M_0 e^{-TE/T_2} \quad (6)$$

where TE = echo time and T_2 is the average T_2 of the tissue. As a result, signal intensity within each volume element in the MR image (voxel) has intensity reduced by the average T_2 of tissue within the voxel according to the echo time of the acquired image. T_2 effects on the signal intensity in two different

Right: image represented in grey scale, the standard viewing method.

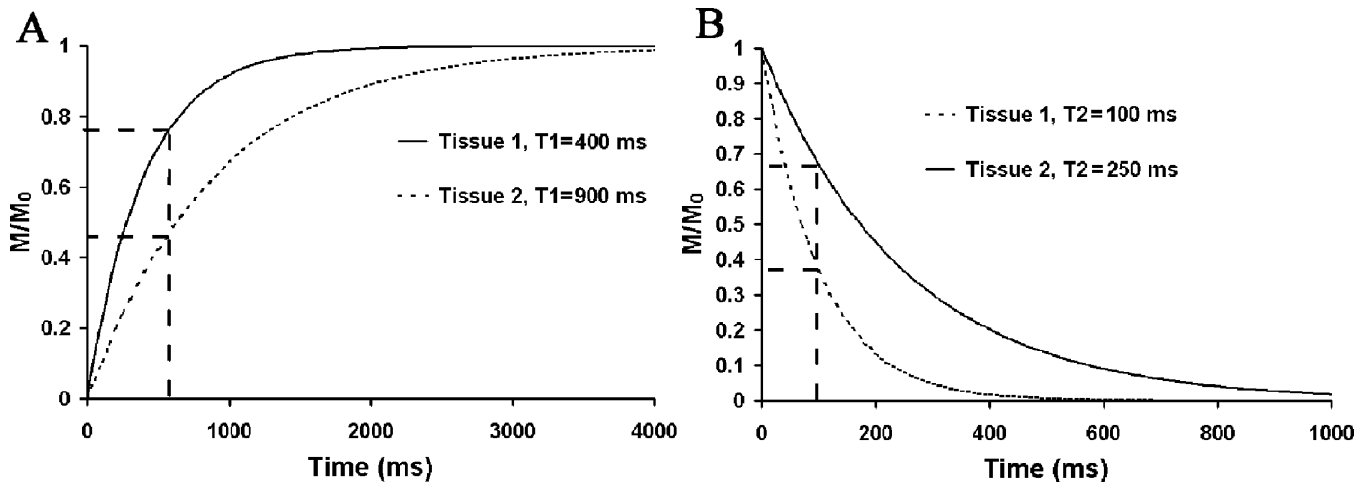

FIGURE 50.7. T_1 and T_2 relaxation curves. A: Recovery of the net magnetization along the Z (B_0) axis after a 90° RF pulse. Dotted lines demonstrate the amount of Z magnetization after a 500 ms delay (TR), proportional to the signal intensity after the second 90° RF pulse. This demonstrates the contrast available in tissue of similar water content (M_0) with different T_1 by reducing TR. B: decay of signal in the transverse plane (X-Y) with echo time (TE). Dotted lines demonstrate the amount of longitudinal (X-Y) magnetization (signal) with a 100 ms spin echo (TE), proportional to the signal intensity during the acquisition of a 100 ms echo. This demonstrates the contrast available in tissue of similar water content (M_0) with different T_2 by increasing TE.

tissues with the same water content (M_0) at an echo time of 100 ms is shown by the dashed lines in Figure 50.7B. Tissue with shorter T_2 (100 ms) refocuses 37% while the longer T_2 tissue (250 ms) refocuses 67% of the original signal, demonstrating significant contrast between tissues of different T_2 using a long echo time acquisition. This demonstrates the contrast available in tissue of similar water content (M_0) with different T_2 by increasing TE. It should also be noted that the signal intensity will be modified at the same time by TR and T_1 through the choice of TR, thus a long TR is typically chosen for purely T_2 weighted images. An example of T_2 weighted imaging and calculation of a T_2 map from multiple TE images from mouse brain can be seen in Figure 50.8.

Multiple echoes may be refocused from one excitation by application of multiple 180° - RF pulses, allowing the acquisition of a series of echoes within one TR. For example, if one echo is acquired at a very early echo time and a second echo is acquired at 100 ms, two images can be acquired. If a long TR is used so that the second echo is purely T_2 weighted, then the first echo with almost no T_2 weighting due to short TE and no T_1 weighting because of the long TR will have contrast based purely on the tissue water content (M_0). This image would be referred to as *proton density weighted*, as the signal intensity in each voxel is proportional to the free water content.

50.2.2.2. Diffusion

Symmetrical application of magnetic field gradients around the refocusing pulse in a spin echo will refocus the signal from static molecules. However, microscopic molecular motion (Brownian motion) will cause dephasing of individual magnetic moments to a degree which is dependent on the freedom of the molecular motion of the water in cells. Freedom of the molecular motion

is affected by the size and shape of the cell and is modified in different cell types. Signal intensity is modified by:

$$ADC_w = \log\left(\frac{S_0}{S}\right) \times b \quad (7)$$

where b is the strength of the diffusion weighting, and ADC_w is the apparent diffusion coefficient of water. A high b -value produces low signal intensity in tissue with a high ADC_w . ADC_w is given in mm^2/s , a value which depends on the temperature and viscosity of the liquid or solid under measure. Since we are typically looking at water in MRI, the diffusion of water is what is measured. Free water, at typical body temperature (38°C) is approximately $2.2 \times 10^{-3} \text{ mm}^2/\text{s}$. However, water in tissue is not free to diffuse as a result of barriers, the cell membrane, and is reduced according to the size and shape of the cell. Shorter distances between cell walls result in a lower diffusion rate. Areas of free water in tissue, such as cerebral spinal fluid or large arteries and veins, show similar diffusion rates to free water. Tissue diffusion values in cells range from 0.6 to $1.0 \times 10^{-3} \text{ mm}^2/\text{s}$. In addition, if the cell is not spherical, which is typically the case in brain, ADC_w is dependent on the direction of diffusion weighting.

Diffusion can be measured separately in various directions by application of diffusion gradients in different directions during individual measurements. In order to obtain an approximation of the average diffusion of water in an asymmetrical cell, measurement of diffusion in three orthogonal directions (for example, along X, Y, and Z directions) are obtained and averaged. However, this is an approximation and a true value can only be obtained by determination of the *diffusion tensor*. This requires a minimum of six individual measurements. This can be understood once the student is familiar with the definition of a tensor.

FIGURE 50.8. T_2 mapping data set, $3/8 T_2$ weighted images with (A) $TE = 15$ ms, (B) $TE = 60$ ms, (C) $TE = 120$ ms and (D) T_2 map created by fitting eight echo imaging sequence to Eq. 6.

A tensor is a mathematical representation of a three dimensional shape using a three by three matrix (Figure 50.9, Eq. 8). The matrix represents the total magnitude of the object in each of nine directions, three of which are equal due to symmetry (e.g. $D_{xy} = D_{yx}$) of the other three cross components, reducing the problem to six dimensions. Hence, six directions of diffusion measurement are the minimum needed to define the diffusion tensor. More measures can be used to improve the accuracy of the measurement through cross correlation of multiple measures.

$$\vec{D} = \begin{pmatrix} D_{xx} & D_{xy} & D_{xz} \\ D_{yx} & D_{yy} & D_{yz} \\ D_{zx} & D_{zy} & D_{zz} \end{pmatrix} \quad (8)$$

The diffusion tensor can then be *diagonalized* to generate a diffusion tensor of the form:

$$\vec{D} = \begin{bmatrix} \lambda_1 & 0 & 0 \\ 0 & \lambda_2 & 0 \\ 0 & 0 & \lambda_3 \end{bmatrix} \quad (9)$$

to determine the primary *eigenvalues* ($\lambda_1, \lambda_2, \lambda_3$) as designated in Figure 50.9. These data can be used to generate pixel by pixel maps of mean diffusivity [$D_{av} = 1/3 \times (\lambda_1 + \lambda_2 + \lambda_3)$] and fractional anisotropy (FA), which is given by the equation:

$$FA = \frac{1}{\sqrt{2}} \sqrt{\frac{(\lambda_1 - \lambda_2)^2 + (\lambda_2 - \lambda_3)^2 + (\lambda_1 - \lambda_3)^2}{\lambda_1^2 + \lambda_2^2 + \lambda_3^2}} \quad (10)$$

FIGURE 50.9. Example of a non-spherical cell with directional dependence of diffusion. Primary laboratory frame of reference is given by x, y and z axes, while the primary axes of diffusion are given as λ_{11} (major), λ_{22} (intermediate) and λ_{33} (minor). Determination of the values of elements of the diffusion tensor allows determination of the magnitude and direction of the primary axes of diffusion (eigenvalues)

FA ranges from zero for a spherical cell to one for an infinitely long cell with zero cross sectional area.

Determination of the principle eigenvalues ($\lambda_1, \lambda_2, \lambda_3$) also allows determination of the principle direction of the cell orientation, which is the orientation of λ_1 in the laboratory (X, Y, Z) frame. Principle direction of the cell can be used to determine fiber orientation in white matter tracts and provide additional delineation of anatomical structure. A map of λ_1 orientation is produced using a red-green-blue encoding in each pixel to represent the direction of the primary eigenvalue, with red representing L-R orientation, blue representing inferior-superior (foot to head) direction and green representing the anterior-posterior direction. Intermediate angles are repre-

sented by linear combinations of the three primary colors. An example of DTI from a mouse brain showing the D_{av} , FA, and RGB encoded λ_1 direction maps are displayed in Figure 50.10.

50.2.2.3. Magnetization Transfer

T_2 of protons on molecules are dependent on molecular motion. Large molecules such as membranes and proteins with slow molecular motion have a very short T_2 (<1 ms). As a result, the linewidth of these molecules is very broad compared to free water. The relationship between linewidth (full width at half maximum) and the T_2 of molecules is given by:

$$\Delta\nu = \frac{1}{\pi \times T_2} \quad (11)$$

where $\Delta\nu$ = linewidth (full width at half maximum). As a result, selective saturation of the protons on large molecules and membranes without affecting the magnetization of free water can be accomplished by a narrow bandwidth RF pulse 4–20 kHz off resonance from the free water signal. Application of the saturation pulse for several seconds is required for a steady state to develop between the saturated macromolecules and exchange of the free water with the hydration layer of the macromolecules, developing a partial saturation (signal loss) in the free water. Signal loss by this mechanism is pro-

portional to the exchange rate of water in the hydration layer of the membranes and macromolecules (Figure 50.11). Determination of the degree of magnetic saturation is done using two images, one without the saturation pulse and one with the saturation pulse. The two images are then divided to determine the spatial distribution of the magnetization transfer ratio (MTR) according to the equation:

$$MTR = \frac{M_0 - M_{ss}}{M_0} \quad (12)$$

where M_{ss} = signal intensity in the presence of steady state saturation and M_0 = signal intensity in the absence of the off-resonance macromolecule saturation. A more complete description of the magnetization transfer effect can be found in a review article by Henkelman (Henkelman et al., 2001).

50.2.2.4. Perfusion

Cerebral perfusion is a marker for metabolic activity of the brain with normal hemodynamic function. Cerebral perfusion has been used extensively for detection of disease and mapping of brain activation in health and disease. MRI methods for mapping cerebral perfusion include (1) qualitative bolus tracking after injection of magnetic contrast agents and (2) quantitative arterial spin-tagging. Each method is described along with the relative strengths and weaknesses, below.

FIGURE 50.10. Diffusion tensor imaging results from a mouse brain imaging study at 7 T. (A) mean diffusivity (D_{av}) (B) Fractional Anisotropy (FA), (C) Color coded FA orientation map.

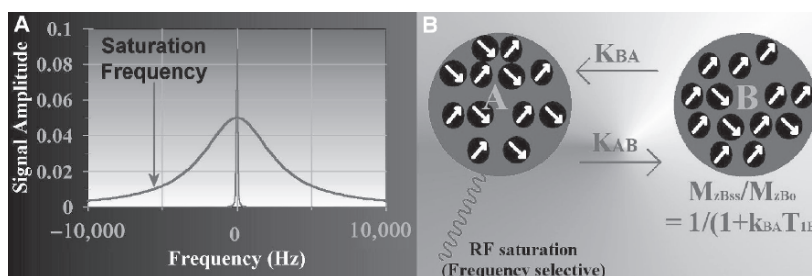

FIGURE 50.11. Magnetization transfer MRI. A: Off-resonance application of a saturation pulse will saturate the signal from macromolecules with short T_2 (broad line) while leaving the narrow water resonance (center line) unaffected. B: Saturation of macromolecules (spin pool A) causes reduction of the free water signal (spin pool B) measured as reduction in intensity of MRI (M_{zBss}/M_{zBo}) inversely proportional to the exchange rate of free water with the water in the macromolecular hydration layer (k_{BA}) times the T_1 of free water (T_{1B}).

50.2.2.4.1. Bolus Tracking Perfusion MRI

Injection of a bolus (typically in 5s or less) of magnetic contrast agent causes signal intensity changes in tissue as the bolus passes through the tissue. Magnetic contrast agents used are typically chelated gadolinium (e.g. Gd-DTPA) complexes, which reduce T_1 and T_2^* of blood and tissue, increasing signal in T_1 and reducing signal in T_2^* weighted images. Advanced rapid magnetic resonance imaging techniques, such as echo planar imaging (EPI) are capable of acquiring multiple slices covering the human brain in 1–3s, allowing the dynamic tracking of the spatial distribution of the injected contrast agent. Signal intensity versus time is then analyzed for each voxel (volume element) in each acquired image to determine (1) time to peak contrast (mean transit time, MTT) and (2) area under the bolus passage signal, proportional to cerebral blood volume (CBV). By mass analysis, cerebral blood flow (CBF) can then be determined by the relation:

$$MTT = \frac{CBF}{CBV} \quad (13)$$

Examples of the signal change over time after bolus injection is shown in Figure 50.12 for a representative normal flow area (MTT_1) and an area with compromised cerebral perfusion (MTT_2). While this method is robust, it suffers from a number of issues related to absolute quantitation of the CBF including, but not limited to partial volume effects, nonlinear relationship between signal intensity change and contrast agent concentration, and determination of the input function of the bolus required for accurate quantitation. In clinical practice, MTT maps are the preferred method for visualizing areas of reduced CBF.

50.2.2.4.2. Arterial Spin-Tagged Perfusion MRI

Quantitation of the CBF can be an important factor in studies of therapeutic intervention. The method of arterial spin-labeled (ASL) perfusion MRI allows quantitative determination of the perfusion rate in units of ml/100 g tissue/min. However, the technique requires exceptional instrumental stability, as the result depends on accurate determination of the difference between two images on the order of a few percent. With the appropriate acquisition parameters to achieve sufficient signal to noise ratio (>100) and current instrument stability, this technique is feasible, especially in high field clinical systems. Currently, arterial spin-tagged perfusion measures are not widely used in clinical settings.

Arterial spin-tagged perfusion MRI is performed by inverting the water protons in the blood of the arteries supplying blood to the tissue of interest. Typically, in brain, the carotid arteries are used as the supply. The original description of the method (Detre et al., 1992; Williams et al., 1992) uses a continuous narrow band RF inversion of the protons in the arterial blood, outside of the imaged slice, before and after excitation to cause a steady-state loss of signal in cerebral tissue. The signal loss is related to tissue perfusion (Detre et al., 1992) by:

$$f = \frac{\lambda}{T_{1app}} \left(1 - \frac{M_{ss}}{M_0}\right) \quad (14)$$

where:

$$\frac{1}{T_{1app}} = \frac{1}{T_1} + \frac{f}{\lambda} \quad (15)$$

FIGURE 50.12. Simulated examples of the time course of signal changes after Gd-bolus administration. Voxelwise analysis of the time series of images is used to create maps of mean transit time (MTT), cerebral blood volume (CBV), corresponding to the area under the curve, and cerebral blood flow (CBF) according to Eq. 13. The delayed curve (MTT_2) corresponds to an area of compromised CBF.

And: f = flow rate, λ = water extraction fraction of tissue from blood (0.8–1.0), M is the MRI signal intensity with (M_{ss} = steady state) and without (M_0) inversion of the protons in the water of the inflowing blood. One potential complication with this method is the effect of magnetization transfer, which occurs with the continuous inversion pulse. This can be balanced by reversing the gradient so that the spatial location of the inversion is above the head when acquiring the M_0 image. This effect is reduced, but not eliminated using more recent pulsed arterial spin labeling techniques (Kim, 1995; Kwong et al., 1995).

50.2.2.5. Relaxometry, Quantitative DWI and Quantitative MT

Perfusion is not the only quantitative method available using magnetic resonance techniques. T_1 , T_2 , apparent diffusion coefficient of water (ADC_w), and MT effects can be quantitatively mapped using the appropriate series of measurements. For example, acquisition of MRI data collected in a series of echo times can be processed to create an image, which is a quantitative map of T_2 (Figure 50.8). Each effect requires its own set of measures, but in principle all methods for modifying signal intensity in MR can be quantified. With the exception of DWI, quantitative mapping is not typically done in a clinical setting due to the time required for additional measures and additional processing required for these data. Advances in MRI are increasing the speed of acquisition, which may allow quantitative techniques to precisely define alterations in neuronal cell, physiology and metabolism as research into multidimensional quantitative MRI defines the sensitivity and specificity of combining these methods to diagnose neurological disease.

50.2.3. Magnetic Resonance Spectroscopy and Spectroscopic Imaging

Prior to the development of MRI in the 1970s magnetic resonance was a well-developed technique used for chemical analysis by spectroscopic analysis of chemicals in sample preparations. This capability has been extended to image guided localized magnetic resonance spectroscopy of tissue in-vivo. Localized spectroscopy uses frequency selective pulses in the presence of a gradient for volume selective excitation and spectroscopic imaging uses phase encoding gradients for spatial encoding of the spectroscopic signals. Many sophisticated pulse sequences have been developed for in-vivo localized spectroscopy and are in use in research and clinical MRI systems worldwide. The difficulty of in-vivo spectroscopy is primarily low spatial resolution due to the low signal intensity. As a result long acquisition times are required to overcome the low signal intensity by signal averaging. Despite this difficulty, in-vivo spectroscopy is unique in the ability to perform non-invasive analysis of chemical composition of tissue without biopsy and allows the serial non-invasive determination

of tissue chemistry with treatment. While any nucleus with a magnetic moment can be studied using MRS and/or MRSI, here we will focus on the most frequently used nucleus for study of brain, the proton (1H).

Frequency shifts of nuclei on different molecules (spectroscopy) are caused by the electron cloud of a molecule. Electron cloud density, and hence field shifts due to the electron cloud, are specific to each molecule. According to the Larmor equation, this results in a frequency shift of the 1H signal for each proton on each molecule, developing a specific “frequency fingerprint” for each molecule. The areas of the peaks are proportional to the concentration of each molecule in the region sampled. These areas are analyzed by fitting the peak areas with one of a variety of spectroscopic analysis software packages. An example of the spectrum from a region of mouse brain acquired at 7 Tesla is shown in Figure 50.13.

1H MRS applies frequency selective pulses in order to generate signal from a single volume of interest defined using MRI. The signal is acquired in the absence of a magnetic field gradient in order to detect the minor frequency shifts due to

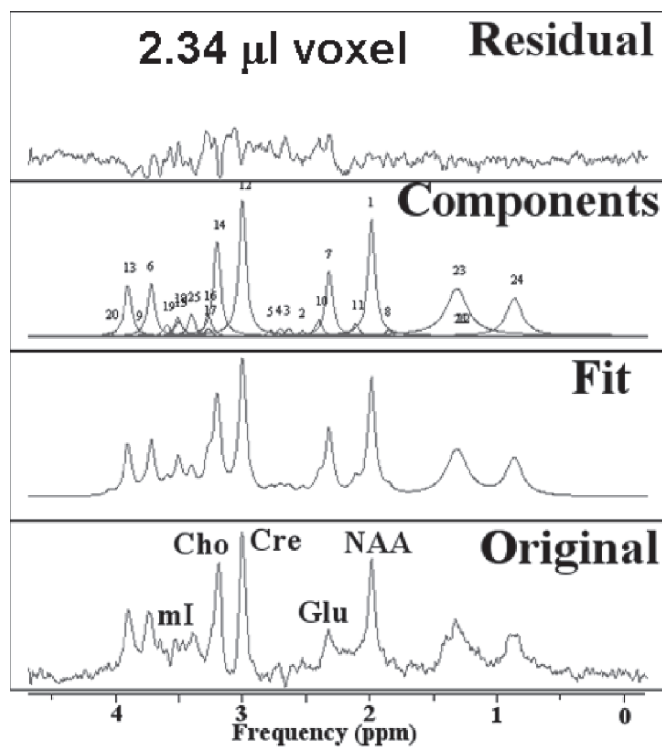

FIGURE 50.13. Example of a 1H MR spectrum from a 1H MRSI data set with a nominal spatial resolution of $2.34 \mu l$ ($1.5 \times 1.25 \times 1.25$ mm) in mouse brain. Original: Spectrum obtained from the region. Fit: Overall fit using models of known spectra of metabolites including, but not limited to N-acetyl aspartate (NAA), glutamate (Glu), glutamine, creatine (Cre), choline (Cho) and myoinositol (mI). Components: Individual peaks contributing to the overall spectra of metabolites and Residual: Subtraction of the fit from the original spectrum. The frequency scale is given in ppm [(frequency/Larmor frequency) $\times 10^6$] to create a frequency scale insensitive to the magnetic field strength.

the electron clouds around atoms (chemical shift). ^1H MRSI uses either a slice selective excitation or volume selective excitation with spatial encoding over the region using phase encoding gradients. This produces an array of volume selective spectra over the region selected. This technique provides improved spatial resolution and the ability to reformat data post-acquisition to allow precise localization of spectra within the slice or volume selected. These advantages come at the expense of acquisition time (typically 15–30 min in human clinical systems).

Several technical challenges need to be overcome for successful application of ^1H MRS/MRSI. The range of metabolite frequencies are relatively narrow, requiring excellent B_0 homogeneity over the region from which data are obtained. This requirement is significantly more difficult to achieve in MRSI (collecting multiple spatially resolved spectra simultaneously over large brain regions) than localized MRS (single spectrum from a small region in the brain). While MRSI is in general used in research laboratories, localized ^1H MRS is most frequently used in clinical applications due to speed of acquisition and reduced technical challenges. ^1H MRS/MRSI requires the suppression of water, as the metabolite concentrations are in the millimolar (mM) concentration range while pure water is 55 M, each water molecule having two equivalent protons, produces a signal intensity of 110 M, five orders of magnitude greater than the signals from the metabolites. Water suppression requires excellent system stability and the elimination of “stimulated echoes” from residual water after application of the suppression technique(s).

Most MRS/MRSI studies of brain use creatine as an internal concentration standard, as creatine has a long T_2 and has relatively constant concentration in most cell types. Advanced methods exist to allow quantitation of the metabolites measured using MRS/MRSI. These methods include the referencing of signal to the internal water signal and referencing in-vivo signal amplitude to signal amplitudes from chemical samples of known concentration. Quantitation requires the correction of signal amplitude for T_1 and T_2 of the metabolites for each acquisition technique. Ideal acquisition parameters for quantitative measurements employ minimum echo time (TE) and a long repetition time (TR) to minimize magnetic relaxation corrections and reduce the chance that changes in relaxation times with pathology could effect the determination of metabolite concentrations.

50.2.4. Computed Tomography Methods, X-Ray Computed Tomography, Single Photon Emission Computed Tomography and Positron Emission Tomography

Computed tomography (CT) techniques share a common mechanism for spatial encoding. A two dimensional projection of the object (similar to a standard x-ray or a single read out in MRI without phase encoding) at multiple angles can be reconstructed into two or three dimensional images. Data

are acquired by rotation of a set of detectors either opposite a radiation source as in CT, or around the subject in the case of internal radiation sources as in Single Photon Emission Computed Tomograph (SPECT) and Positron Emission Tomograph (PET). This method can also be used with MRI by combining gradients to provide a series of readouts at multiple angles (typically from 64 to 256), however modern MRI acquisition techniques are more efficient, therefore this technique is rarely used in MRI.

Reconstruction of images from tomographic methods are performed using the reverse Radon transform (Herman, 1980) which uses the series of angular projections to reconstruct images. The resulting data set can be displayed as a rotating three-dimensional movie or resliced in any direction to display a series of two-dimensional slices.

X-ray CT uses a high intensity X-ray beam and a series of detectors that rotate around the subject. Modern CT scanners use multiple sets of X-ray sources and detectors to simultaneously acquire multiple slices (currently, up to 64) to speed acquisition. This allows full brain coverage at high spatial resolution in a matter of seconds. High doses of X-ray (about 5 rads) are typical exposures for this type of exam.

SPECT detects emitted gamma rays from radioactively labeled molecules or cells. The position of the emitted gamma ray is determined by an array of crystal detectors covered by a collimator, which limits the angles from which gamma rays can enter the detector. Collimators consist of either a lead shield with a pinhole for three-dimensional tomographic acquisitions or a series of slots for two dimensional, planar (2D) acquisitions. Sensitivity of SPECT is limited by the area of the collimators opening. This concept can be understood by thinking of a pinhole collimator placed at a distance from the center of the subject being scanned. For example, if a 1 mm diameter pinhole is placed 10 cm from a mouse, the area covered on the surface of the sphere prescribed by the opening of the collimator (radius = 10 cm) is 1257 cm^2 ($4\pi r^2$). The gamma ray capture area of a 1 mm pinhole (0.5 mm = 0.05 cm radius) is 0.008 cm^2 (πr^2). Emission of gamma rays from the radioactive tracers is isotropic (equal probability of travel in any direction) the fraction of total gamma rays captured by the pinhole will be $0.008/1257 = 6 \times 10^{-6}$. Sensitivity can be increased by increasing the size of the pinhole, at the expense of spatial resolution or increasing the number of detectors in order to increase the counts for each angular projection. Recent technical developments have introduced multiple pinhole collimators (9–12) per detector array and multiple detectors for a significant increase (factor of 40) in detection sensitivity. The relatively low sensitivity of SPECT is typically compensated by using high doses of radioactive label, typically 50–500 microcuries to allow detection of labeled molecules or cells down to the nanomolar (10^{-9} M) concentration range.

PET uses positron emission to increase sensitivity of detection over SPECT. Once a positron is emitted from the radioactive atom on the labeled molecule, it travels a short distance (2–5 mm, depending on the energy of the emitted positron)

and undergoes an annihilation reaction with an electron. Annihilation, occurs because the positron is antimatter to the electron. The reaction creates two 0.511 MeV gamma rays which then travel 180° away from each other. PET scanners employ a ring of detectors (typically 1024) and coincidence detection (simultaneous detection of two gamma rays) to improve detection sensitivity and filter out background radiation. As a result of the high capture cross section of the ring of detectors and the virtual elimination of background radiation, sensitivity is enhanced approximately four orders of magnitude compared to SPECT. This allows detection of lower concentrations of tagged molecules and cells down to the picomolar (10^{-12} M) concentration range with lower doses of radioactivity injected into the subject (typically around 10 microcuries).

Positron emitting nuclides have very short half lives, on the order of minutes to two hours. This makes operation of a cyclotron and a radiochemistry laboratory essential to the use of PET scanners. ^{18}F is the longest radionuclide with a half-life of 1.87h, making a central production facility within a city feasible for radiopharmaceuticals employing this nuclide. Most clinical PET facilities have on-site cyclotrons and radiopharmaceutical laboratories to allow the use of short-lived isotopes in clinical studies.

One difficulty with some SPECT and PET images is the potential lack of anatomical detail, especially in studies of receptor distribution where widespread distribution of the label in tissue may not occur. Two methods are used to overcome this problem, coregistration to anatomical images and simultaneous acquisition of anatomical images. Coregistration is typically performed for images lacking anatomical detail using fiducial markers visible in both scan sets to allow spatial registration of the SPECT or PET images to anatomical images such as CT or MRI. A more robust and time efficient method is the use of SPECT/CT or PET/CT scanners in which anatomical and tracer studies are acquired simultaneously providing anatomical images acquired simultaneously with SPECT or PET image acquisition.

50.3. Information Content

Effective use of imaging methods requires the understanding of the type of information available from each scanning technique. As neuroscientists, it is necessary to consider pathophysiological correlates of disease when designing and interpreting imaging studies. Some current research is focusing on correlation of histopathology and neuroimaging in animal models of neuronal disease (Boska et al., 2005; Nelson et al., 2005) which will serve to validate and refine the interpretation of imaging results. Consideration of expected pathology is required for experimental design and application of the most appropriate imaging methods to specifically address a particular physiological question. In the previous section, the basic principles of imaging methods were presented to allow the neuroscience student to understand the signal source and

methods used to obtain imaging information. We will build on this to obtain a broad view of the basic capabilities of each imaging method and examples of the information available by use of the method.

50.3.1. Magnetic Resonance Techniques

The wide variety of morphological, physiological, and biochemical information available from the multitude of MR techniques, which allow sophisticated combinations of methods to be applied to individual neurological studies. This is one reason that MRI is often the best choice for neuroimaging studies, as the combination of multiple methods in one study can provide a wide array of coregistered information on the effects of disease and experimental therapies on brain function and biochemistry.

50.3.1.1. T_1 , T_2 , and Proton Density Weighted MRI

The use of T_1 , T_2 and proton density weighted images comprise the bulk of clinical MRI scans due to the ability to detect cellular alterations in tissue and determine morphological changes with exquisite soft tissue contrast. As a result, brain lesions, especially white matter lesions, tumors, and damaged regions from vascular disease are visible typically as dark areas on T_1 and bright areas on T_2 weighted images.

While these imaging modalities are sensitive to cell type, the combination of T_1 , T_2 and proton density are not specific to cell type or the type of alteration in normal cell physiology. Improved specificity can be obtained by combining these MRI scans with other types of information including clinical manifestations of disease, other neuroimaging scans and advanced analytical methods to improve diagnostic accuracy.

Use of T_1 and T_2 weighted images can be used to determine grey matter, white matter, and CSF content in neuroimages and determine the volume of multiple brain structures. Reduced volumes of gray matter, basal ganglia, and subthalamic nuclei have been found in various neurological diseases, the details of which are beyond the scope of this chapter. Good reviews are available for findings from HIV dementia (Boska et al., 2004), Alzheimer's disease (Kantarci and Jack, 2004; Chong and Sahadevan, 2005; Masdeu et al., 2005), Parkinson's disease (Krabbe et al., 2005; Seppi and Schocke, 2005) and the hippocampus in a wide range of neurological diseases (Geuze et al., 2005). Generally, decreased volumes of affected brain structures, such as the substantia nigra in Parkinson's disease and atrophy of the grey matter in dementia such as Alzheimer's disease have been found in these studies. Scientific investigation continues into this area and as imaging and analysis software improves and the definition of changes due to disease are better defined, the use of these data in clinical diagnosis and patient management will be put into practice.

Recent studies have also shown that neuronal depolarization will cause increases in T_1 and T_2 . T_1 was shown to increase by 13% while T_2 increased by 88% at 1.5 T in a rat model of spreading depression (Stanisz et al., 2002). While

this effect has not been studied in great detail, it is possible that this effect could be a source of detecting abnormalities in neuronal polarization with careful quantitation of T_1 and T_2 in neuronal diseases.

It will be apparent to the neurosciences student that this field, even in the case of one of the best characterized and most studied imaging modalities, standard MRI, that new information is acquired rapidly, advanced through the acquisition of data in biologically characterized animal studies and translated to well characterized human disease states. This process is cyclical, as advances in imaging methods will improve the classification of human neurological disease, leading to improved characterization and more refined human study. Advances in data processing methods through computer science advances, developments of imaging data correlated with biological data, and advanced statistical analyses will be primary areas of imaging research for the advancement of disease characterization and detection sensitivity and specificity of imaging methods for many years to come.

50.3.1.2. Diffusion Weighted Imaging (DWI)

The primary use of DWI in clinical practice is detection of acute stroke lesions. Within minutes after a stroke, a low diffusion area of brain is visible in the majority of stroke cases. In a diffusion weighted image, this appears as a bright area, as tissues with low diffusion lose less signal during the diffusion weighting. Signal abnormalities usually do not appear before 16h on T_1 and 8h on T_2 weighted images (Yuh et al., 1991). Diffusion weighting requires a long echo acquisition, so the appearance of bright areas on DWI can be either from low diffusion or increased T_2 signal which occurs in late acute to chronic infarcts. In order to eliminate confusion from this effect, two images are acquired, one with no diffusion weighting and one (or more) with high diffusion weighting. This allows the calculation of a parametric image of the apparent diffusion coefficient of water (ADC_w). Acute stroke lesions typically appear as bright on DWI and dark on ADC_w maps. As stroke lesions age, the cells in the lesion begin to break down after cell death and leave an area of edema. As the stroke lesion progresses towards cellular breakdown and edema, both diffusion and T_2 increase. After days to weeks, the diffusion “pseudonormalizes” to a value equivalent to normal brain tissue, progressing to high diffusion. A combination of ADC_w , T_1 and T_2 maps can be used to characterize the age of the stroke lesion (Nagesh et al., 1998; Welch et al., 2001).

Diffusion is altered in other types of brain lesions and is not specific for stroke (Wang et al., 1998). The range and types of diffusion alterations are an area of active research. Combination of DWI, T_1 , T_2 , MT and perfusion may serve to more precisely characterize lesions from neurological diseases (Dijkhuizen and Nicolay, 2003).

50.3.1.3. Diffusion Tensor Imaging

Multiple metrics can be calculated from diffusion tensor imaging (DTI) data, typically mean diffusivity (D_{av}) and fractional

anisotropy (FA). Analysis of brain pathology using DTI metrics can be performed by lesion analysis, whole brain histograms of FA and D_{av} , tractography and analysis of otherwise normal appearing white matter. Fractional anisotropy has been studied in numerous diseases and detects abnormalities in otherwise normal appearing white matter by conventional MRI. This demonstrates the increased sensitivity to disease within the brain that DTI metrics can resolve. Abnormal FA in normal appearing white matter has been found to occur in multiple sclerosis, radiation injury, aging, schizophrenia, and amyotrophic lateral sclerosis (Foong et al., 2000; Filippi et al., 2001; Cosottini et al., 2005; Kitahara et al., 2005; Salat et al., 2005). Fractional anisotropy maps or DTI in general for acute stroke analysis has not been found to add significant clinical information in the setting of acute stroke therapy, although, active investigation in this area continues.

Brain lesion analysis is also an active area of research. DTI metrics have been found to help differentiate between tumor types and promises to provide a sensitive method for abnormal tissue characterization. Fractional anisotropy has already been found to correlate with the cell density of brain tumors (Beppu et al., 2003; Beppu et al., 2005). The ability of FA to correlate with cell density likely accounts for the sensitivity of FA to tissue typing in brain lesions. Fractional anisotropy has been found to differentiate between low grade and anaplastic astrocytomas, to help differentiate between brain metastasis and high grade gliomas, and there is evidence that FA may help to detect tumor infiltration not visible by conventional MRI (Holmes et al., 2004; Tsuchiya et al., 2005; Goebell et al., 2006). Other DTI metrics have been utilized in brain lesion analysis and the early findings point to the breadth of future possibilities.

The diffusion tensor data can also be utilized to perform white matter tractography (Jellison et al., 2004). Tractography is the virtual dissection of white matter tracts within the brain and provides a novel method to analyze the white matter tracts in disease states. Tractography in combination with other DTI metrics and other MRI techniques such as perfusion and spectroscopy opens the door for currently uncharted areas of research. Previously there was nearly no indication of the intricate connections present in the white matter on conventional MRI. DTI tractography can be used to map out numerous fiber tracts including but not limited to the corticospinal tracts, superior occipitofrontal fasciculus, inferior occipitofrontal fasciculus, uncinate fasciculus, superior longitudinal (arcuate) fasciculus, inferior longitudinal (occipitotemporal) fasciculus, (Jellison et al., 2004). With advancements and refinements in acquisition of DTI, performing tractography provides further advances in the “virtual dissection” of the white matter tracts.

A very exciting and innovative application of DTI and tractography that will have profound clinical application is analysis of brain lesions. There has already been early work defining tumor growth and metastases within major white matter tracts (Witwer et al., 2002; Yu et al., 2005; Hlatky et al.,

2006). This application will provide measures of white matter tract displacement and tumor invasion that will be defined with great specificity. Previously estimates of white matter tract invasion could only be made by gross estimates of where the white matter tracts were expected to lie based on cross-sectional MRI or CT studies. However, current methods of DTI tractography can not reproducibly demonstrate the true size of fiber bundles (Kinoshita et al., 2005).

50.3.1.4. Magnetization Transfer (MRI)

Magnetization Transfer (MT) MRI is sensitive to areas of demyelination, as the MT effect from myelin is particularly strong. The use of MT MRI for the detection and characterization of lesions due to multiple sclerosis has been well studied (Atalay et al., 2005). Quantitative analysis of the magnetization transfer ratio (MTR) of gray matter in the earliest stages of the disease demonstrate statistically significant reduction in the basal ganglia of these patients (Audoin et al., 2004). In general multiple advanced MR techniques, including MTR maps, ^1H MRSI, quantitative T_1 and T_2 mapping, diffusion tensor imaging, and studies of blood flow have lead to a more sophisticated understanding of the disease from the early view of simply an immune mediated demyelination process to the understanding of disease effects on neurons, axons, and oligodendrocytes (Minagar et al., 2005).

MT MRI has been shown to be sensitive to other minor structural abnormalities caused by neurological disease. MTR maps were analyzed with a statistical package demonstrated that areas of epileptic activity which were not detected visually had statistically reduced MTR in the epileptic focus (Rugg-Gunn et al., 2003). When MT MRI was combined with DWI, reductions in both MTR and ADC_w were found in the epileptic focus of patients (Ferini-Strambi et al., 2000).

More advanced quantitation methods for MT MRI have been shown to be sensitive to white matter tracts and axonal density (Yarnykh and Yuan, 2004) as well as being sensitive to the earliest events in stroke lesions (Jiang et al., 2001) including early detection of ruptures in the blood-brain barrier which may be susceptible to hemorrhagic transformation (Knight et al., 2005).

50.3.1.5. Perfusion MRI

Perfusion in cerebral tissue with normal vasculature is controlled by metabolic demand, allowing use of regional quantitative perfusion measures to detect neurodegeneration in a variety of diseases. Perfusion measures have been a cornerstone of nuclear medicine (SPECT and PET) studies for characterizing brain regions affected in neurological disease.

MRI perfusion studies have been used primarily to study perfusion deficits in stroke lesions. The mismatch between DWI and perfusion deficit may represent tissue at risk for damage (Neumann-Haefelin et al., 1999) which may be salvaged using thrombolytic therapy. However this interpretation of mismatch between DWI and perfusion MRI is controversial

and study of this effect is an area of active research (Rowley, 2005).

Brain tumor imaging is a growing area of clinical application of MRI perfusion studies. MRI perfusion studies have been found to provide valuable information when evaluating multiple facets of the imaging of gliomas, metastatic disease, abscesses, radiation necrosis, and meningiomas. The grading of gliomas pre-operatively has been found to be enhanced by utilizing MRI perfusion (Law et al., 2003; Law et al., 2004). Also, the determination if a lesion is a high-grade glioma or a metastatic lesion, the differentiation of which is markedly important clinically, can be facilitated utilizing MRI perfusion as well as MRS (Law et al., 2002). The differentiation of an abscess from a ring enhancing glioma is also potentially facilitated by MRI perfusion (Holmes et al., 2004). A significant problem that can occur with MRI perfusion is leakage of the contrast through the blood brain barrier on the first pass so that the appearance of the perfusion curve is distorted and a true evaluation of the tumor perfusion is not obtained. This is unfortunately a potentially frequent occurrence since blood brain barrier disruption is a hallmark of high-grade gliomas.

Studies of perfusion deficits in other neurological diseases have been hindered in MRI by the difficulties in quantitation of cerebral perfusion in bolus tracking perfusion measures. Arterial spin-labeling techniques have been successfully employed in recent studies of human disease including Alzheimer's disease (Alsop et al., 2000; Johnson et al., 2005). Arterial spin-labeling perfusion measures are greatly enhanced at high field due to increased signal to noise and increased T_1 , improving reliability of the technique (Wang et al., 2002). Increased availability of high field (3 T and above) clinical MRI systems will allow greater use of quantitative perfusion measures to assess neurodegenerative disease in clinical practice.

50.3.1.6. ^1H MRSI

Proton MRS detectable metabolites are primarily N-acetyl aspartate (NAA), choline (Cho), creatine (Cre), glutamate (Glu), glutamine (Gln), and myoinositol (mI). NAA is found predominately in the neurons and the typical physiological intraneuroanal concentrations is 9–12 mM (Urenjak et al., 1992), and as such is widely used as a marker of neuronal density. However, biochemical studies suggest the possibility of multiple roles for the metabolite NAA including an energy metabolism reserve (Heales et al., 1995; Bates et al., 1996), a supply of acetyl-Coenzyme-A for the tricarboxylic acid cycle in mitochondria (Mehta and Namboodiri, 1995; Miller et al., 1996), a source of N-acetyl-aspartylglutamate (a neuropeptide that is involved in neurotransmission), a source of glutamate (a neuroexcitatory molecule which itself is a source for gamma-amino butyric acid) (Miller et al., 1996) and a role as an osmotic regulator (Taylor et al., 1995). NAA is synthesized exclusively in the mitochondria of neurons and decreases in NAA may be due, at least in part, to mitochondrial dysfunction (Goldstein, 1969; Heales et al., 1995; Mehta and Namboodiri, 1995). Neuronal cell death induces

an irreversible loss of NAA due to localization of NAA in the neuron (Urenjak et al., 1992), while reversible loss of NAA is likely associated with reversal of mitochondrial dysfunction or replacement of damaged mitochondria within the neurons. The choline peak (Cho) is due to total levels of mobile choline containing compounds. Cho mainly consists of glycerophosphocholine and phosphocholine, compounds involved in phospholipid metabolism in brain tissue. Choline concentrations are known to be elevated in multiple sclerosis (MS) during periods of active demyelination (Simone et al., 2001). Total creatine (Cre) concentration [Cre] is the amount of creatine plus phosphocreatine in brain tissue. Cre is part of the creatine kinase energy metabolism buffer system used to maintain ATP levels in times of acute mismatch between oxidative adenosine triphosphate (ATP) supply and ATP demand. The [Cre] reflects the health of systematic energy use and storage (Miller, 1991). Total [Cre] tends to remain relatively constant in most cell types, although the [Cre] in glial cells is four times that in neuronal cells (Petroff et al., 1995) and is known to be elevated in multiple sclerosis and epilepsy where gliosis is significant. mI may also act as a marker of glial cell numbers (Chang et al., 1999) and as an osmoregulator or intracellular messenger (Ross, 1991).

Lactate [Lac] is seen as a result of numerous etiologies such as secondary to anaerobic glycolysis in tumors. Hypoxic insult can also cause an elevation of Lac. Lipid occurs in the same spectral region as Lac and can obscure Lac. It is often difficult to separate these two peaks from each other but lactate has a classic doublet appearance. The presence of lactate can be confirmed by utilizing a TE of 136 ms causing the lactate doublet to invert (appear upside down in the spectrum) due to j-coupling (Yablonskiy et al., 1998). Lipids indicate the presence of necrosis or disruption of myelin sheaths. A higher level of lipid in a brain tumor generally indicates a high-grade malignancy. Lipids are best seen on spectra obtained with short TEs. However, contamination of the spectrum with scalp fat or bone marrow in the skull can result in a lipid peak, so care must be taken to interpret spectra with an understanding of the technical details of the acquisition.

¹H MRS and MRSI have been demonstrated to be sensitive methods for early detection of neuronal dysfunction or loss, reflected by loss of NAA. The application of MRS adds specificity to the diagnosis of a lesion relative to MR imaging alone (Ross and Michaelis, 1994; Howe and Opstad, 2003; Nelson, 2003).

MR spectroscopy is used extensively in clinical practice to help differentiate tumor from non-tumor lesions in the brain. The Cho/Cr and NAA/Cho ratios can be utilized to help accomplish this task (Poptani et al., 1995; Moller-Hartmann et al., 2002). Increased Cho/Cr and decreased NAA/Cho are positive indications of a brain tumor (Poptani et al., 1995; Moller-Hartmann et al., 2002). The lipid and lactate peaks are more variable in tumor and non-tumor lesions but can also aid in tumor diagnosis. There are a number of disease processes, such as multiple sclerosis plaques, that cannot always be differentiated by spectroscopy from a brain tumor.

Tumor grading can be challenging with MR spectroscopy and there are overlaps between the appearance of the spectra from different grades of astrocytomas and oligodendrogliomas. The Cho peak and the Lip/Lac peaks tend to demonstrate increases as an astrocytoma progresses from low-grade to glioblastoma multiforme (GBM) (Nelson et al., 2002; Howe et al., 2003). Due to the complexity and necrosis in GBMs the peak values are somewhat variable (Howe et al., 2003). The Cr and the NAA peaks are decreased in low-grade GBM (Nelson et al., 2002). Myo-inositol is increased in low grade astrocytomas and is decreased in high grade astrocytomas (Castillo et al., 2000). The Lip and Lac peaks can be used to separate low-grade from high-grade (anaplastic) oligodendrogliomas in which they have been found to be significantly elevated (Rijpkema et al., 2003). In low grade oligodendrogliomas, glutamate and glutamine have been found to be elevated and this may help to differentiate oligodendrogliomas from other brain tumors such as astrocytomas (Rijpkema et al., 2003).

Gliomatosis cerebri can demonstrate subtle changes on MR spectroscopy. The subtle changes likely result in part from the infiltrative nature of the tumor and that a component of the spectrum represents normal brain. It has been described that the Cho/Cr levels may be normal and that only an elevated MI level will be detected in gliomatosis cerebri (Mohana-Borges et al., 2004). Also, there may be normal Cho/Cr levels, associated decreased NAA and Lip/Lac present (Pyhtinen, 2000).

It can be critical to obtain a MRSI study over the entire complex heterogeneous areas of a brain lesion in order to institute appropriate therapy, plan surgeries and accurately diagnose the brain lesion (Nelson, 2003). MRSI helps to define the spatial heterogeneity that is present in brain lesions and also contributes to defining the spatial extent of brain lesions. Two-dimensional MRSI performed at multiple levels or a single three-dimensional MRSI sequence can be performed to accomplish this task. MRSI can be used to help differentiate infiltrating primary brain tumors from metastatic disease. With metastatic tumors in the brain the spectral abnormality will not extend beyond the area of enhancement but with primary infiltrating brain tumors the spectral abnormality will persist outside of the area of enhancement.

Diagnosing radiation necrosis versus tumor recurrence is also a useful and accurate application of intracranial MR spectroscopy (Schlemmer et al., 2001; Nelson, 2003). Radiation necrosis will have large Lip and Lac peaks without elevated Cho whereas tumor would have elevated Cho. MRSI is particularly useful for distinguishing recurrent tumor versus radiation necrosis given its ability to spatially sample multiple areas of a lesion (Chernov et al., 2005).

50.3.2. Computed Tomography

Computed tomography (CT) of the brain revolutionized the care of neurological patients and was instrumental in helping to elucidate many disease processes after its introduction.

However, the advantages of utilizing CT to image the brain have been greatly reduced by MRI's markedly better CNS contrast, MRI's physiologic imaging abilities and the metabolic information obtainable from PET or SPECT imaging. CT still plays an important role in the setting of trauma due to its proven ability to detect hemorrhages that require surgical intervention. CT also is advantageous in the trauma setting since it is often too difficult to adequately screen a patient for an emergent MRI and to monitor the acute trauma patient in the MRI scanner. Hemorrhages appear hyperdense acutely on CT and CT can accurately demonstrate subdural, epidural, parenchymal, intraventricular, and subarachnoid hemorrhages. CT exquisitely demonstrates the skull and skull base and is unsurpassed in detecting fractures.

CT has limited ability to differentiate the type of insult occurring in the brain and usually a brain lesion results in a lower density than the surrounding tissues. Lesions with calcification, hemorrhage, or high cellularity (such as lymphoma, primitive neural ectodermal tumors, medulloblastomas or small cell lung cancer metastases) will result in increased density. Iodinated contrast agents help evaluate lesions in the brain for blood brain barrier breakdown and contrast helps improve lesion conspicuity. However, a gadolinium contrast enhanced MRI is more sensitive to detecting evidence of blood brain barrier breakdown than a contrast enhanced CT (Mihara et al., 1989).

CT has been shown to be able to detect early changes in the development of Alzheimer's disease (de Leon et al., 1993), although it has been found that other technologies, such as MRI and PET imaging, show changes better than CT. Also, in the analysis of seizure patients CT can demonstrate numerous parenchymal pathologies but a MRI examination is often a better evaluation (Heinz et al., 1989). CT is particularly useful when evaluating seizure patients for detecting small calcified lesions such as in neurocysticercosis, periventricular calcifications of tuberous sclerosis, or the cortical calcifications present in Sturge-Weber syndrome.

A non-contrasted CT is often performed as the initial evaluation of the brain in the stroke patient secondary to CTs availability and CTs ability to exclude hemorrhage. The non-contrasted brain CT is also the neuroimaging study that was utilized in major stroke treatment studies (Furlan et al., 1999). The non-contrasted brain CT offers limited information compared to MRI but recently with the development of CT perfusion of the brain additional information can now be obtained. CT perfusion moves CT imaging from static morphological imaging to providing physiological data that has already been shown to be useful for stroke imaging (Lev et al., 2001; Wintermark et al., 2006).

Multiple parameters can be calculated with CT perfusion imaging of the brain and include cerebral blood flow, cerebral blood volume, time-to-peak, and mean transit time (Wintermark et al., 2006).

The information obtainable with CT perfusion is very powerful especially when combined with computed tomographic

angiography (CTA). These data can be used as a substitute for MRI when evaluating stroke patients (Schramm et al., 2004).

CTA is a method for relatively non-invasively imaging the arteries and veins of the brain. The ability to create a CTA examination of the circle-of-Willis became possible with the advent of spiral CT, however, the quality of the examinations and the robustness of the techniques were greatly improved with the advent of multislice CT. The speed of acquisition continues to advance at a remarkable rate. With a 64-slice CT scanner the whole brain can be imaged in seconds with submillimeter slice thickness. The ability to scan fast when performing CTA of the brain cannot be overstated given that a main application is evaluating patients with subarachnoid hemorrhage for the presence of cerebral aneurysms. Patients with subarachnoid hemorrhage often have mental status changes that make it difficult or impossible for them to follow directions and lie still for an extended period of time. CTA is now often used to screen patients with subarachnoid hemorrhage for cerebral aneurysms in order to determine if an aneurysm is present and what type of therapy (surgical clipping or intravascular coiling) is appropriate.

The evaluation of acute stroke patients with CTA is being performed to evaluate for the underlying vascular etiology (Smith et al., 2006). CTA can nicely demonstrate areas of stenosis or thrombosis in the arteries. The presence of a large vessel intracranial occlusion in an acute stroke patient has been found to even be an independent predictor of poor outcome (Smith et al., 2006). Also, computed tomographic venography has been found to be beneficial for evaluating patients for the presence of venous thrombosis.

50.3.3. Single Photon Emission Computed Tomography

Single Photon Emission Computed Tomography (SPECT) in general has a greater clinical availability compared to Positron Emission Tomography (PET). Secondary to SPECT's greater availability, proven capabilities and its lower cost it is an often used clinical and research imaging modality. SPECT is very useful for evaluating brain perfusion and has demonstrated utility for evaluating the brain perfusion of many disease processes including stroke, Alzheimer's disease and other dementias, Parkinson's disease, seizure patients, and brain tumors. Perfusion is just one parameter that can be measured with SPECT and there are many different radiotracers that can be used with SPECT for neurotransmitter system imaging (Kegeles and Mann, 1997).

Thallium-201 SPECT and fluoro-deoxyglucose (FDG) PET are both used to help differentiate residual brain tumor and brain tumor recurrence from radiation necrosis. Thallium-201 SPECT has been found to be just as good or even better for tumor detection than FDG PET (Kahn et al., 1994; Maria et al., 1998; Stokkel et al., 1999). Thallium-201 SPECT can also be utilized to help differentiate lymphoma from toxoplasmosis which is an important question in immunocompromised

patients particularly patients with human immunodeficiency virus (Young et al., 2005). Difficulties have been found when evaluating immunocompromised patients in the clinical setting and this may in part be due to the difficulty of evaluating small lesions (Licho et al., 2002).

There are numerous psychiatric applications of SPECT and these include evaluation of major depressive disorder, obsessive compulsive disorder, and schizophrenia (Novak et al., 2005; Topcuoglu et al., 2005; Alves et al., 2006). Studies have been performed evaluating these diseases and other psychiatric disorders at their initial presentations, during disease progression, and what the associated imaging changes are with medical intervention. There are many continued opportunities for investigation utilizing SPECT in psychiatry particularly whether it is utilizing a newly formulated radiotracer, utilizing advanced analytical techniques or combining SPECT data with MRI data.

SPECT has been found to be quite useful when evaluating patients with seizures (McNally et al., 2005; Tae et al., 2005). SPECT imaging is commonly used for the ictal study of seizure patients in order to define areas that are the seizure focus. It has in general been much easier to perform ictal SPECT than ictal PET. Advanced analytical techniques of SPECT imaging have helped to improve the data analysis and utilization of the SPECT data in the evaluation of seizure patients but further improvements and validation of the techniques are required (Knowlton et al., 2004).

50.3.4. Positron Emission Tomography

The information obtained from a Positron Emission Tomography (PET) scan depends on the radiotracer used and there is a wide array of radiotracers that can be used by the neuroscientist when analyzing the brain. PET using fluoro-deoxyglucose (PET-FDG) has wide clinical and research availability and has many applications in the neurosciences. PET-FDG can be used to study numerous pathologies including tumors, strokes, dementia, addiction disorders, schizophrenia, depression, seizures, and developmental abnormalities. There are a greater number of tracers that have been developed for PET than SPECT that allow in-vivo mapping of numerous neurotransmitter systems in humans (Kegeles and Mann, 1997).

PET-FDG has been used extensively to investigate brain tumors including astrocytomas, oligodendrogliomas, meningiomas, lymphomas, metastatic disease, and the differentiation of tumor necrosis from tumor recurrence. In the evaluation of brain tumors PET-FDG has been found to help determine the grade of malignancy and can provide predictive prognostic information (Kaschten et al., 1998; De Witte et al., 2000; Borgwardt et al., 2005). Carbon-11-methionine has also been found useful, if not better, than PET-FDG for predicting histological grade and the prognosis of gliomas (Kaschten et al., 1998). Carbon-11-methionine is felt to be superior to FDG secondary to its sensitivity and clearer delineation of tumors (Pirotte et al., 2004; Van Laere et al., 2005), although, it is not as readily available for clinical use and investigation as FDG.

Thallium-201 SPECT as mentioned in the previously section also has been shown to perform as good if not better than PET-FDG in brain tumor analysis (Kahn et al., 1994; Maria et al., 1998; Stokkel et al., 1999).

Evaluating dementias with PET imaging is another area that has generated a lot of attention as well as clinical and research applications. The ability of PET scanning to help differentiate whether a patient has Alzheimer's disease has generated great interest due to the large number of individuals affected. PET-FDG is the radiotracer that is routinely utilized in the evaluation of dementias. PET-FDG can help to determine if a patient has Alzheimer's disease, mild cognitive impairment, and if a patient with mild cognitive impairment is likely to convert to Alzheimer's disease (Mosconi et al., 2004; Anchisi et al., 2005). Frontal-temporal dementia, vascular dementia and lewy body dementia diagnosis can also be facilitated with PET-FDG (Mirzaei et al., 2003; Higdon et al., 2004; Kerrouche et al., 2006).

The utility of imaging patients who have or potentially have Parkinson's disease can be valuable in multiple ways including early confirmation of the diagnosis, predicting clinical course, and to evaluate the results of therapies. When evaluating Parkinson's disease both PET-FDG and 6-[(18F)]fluoro-L-dopa (FDOPA), a common presynaptic dopaminergic radiotracer, can be effectively utilized (Kaasinen et al., 2006). FDG and FDOPA PET has been shown to be an indicator of the severity of Parkinson's disease and at patient's initial evaluations can be used to predict the clinical prognosis (Kaasinen et al., 2006). The differentiation by PET-FDG of Parkinson's disease, progressive supranuclear palsy and multiple system atrophy may also be facilitated given differences of metabolism that have been found (Juh et al., 2004). Therapeutic induced changes of brain metabolism can be evaluated for both surgical and medical interventions (Hilker et al., 2002; Hershey et al., 2003; Zhao et al., 2004). These type of inquiries provide knowledge that can be used to judge an intervention's success, how an intervention's success may have been produced, and potentially to predict early on in a treatment paradigm what long term success may be obtained.

There are several possible applications of PET imaging for seizure evaluation. PET-FDG again has been the predominant radiotracer that has been utilized for seizure evaluation, although, numerous radiotracers have been studied. Pre-operative evaluation of temporal lobe epilepsy is a frequently performed application of PET-FDG and PET-FDG is able to help predict the success of surgical intervention and can help guide the type of surgical resection (Theodore et al., 1997; Kim et al., 2003). PET as already mentioned usually studies the seizure patient in the interictal state since it is difficult to perform ictal PET studies. PET-FDG can also be a predictor of verbal decline after anterior temporal lobectomy – a surgery performed to help control complex partial seizures (Griffith et al., 2000). It has also been shown that PET-FDG is beneficial for evaluating for seizure foci in a general epilepsy population (Swartz et al., 2002).

Summary

This chapter has presented an overview of the mechanisms and applications of neuroimaging for the student of neuroscience with a view towards providing an understanding of the potential of neuroimaging techniques in neuroscience research. As the field progresses, methods for whole brain analyses, development of new detection methods and new radiotracers combined and coregistered will provide whole brain non-invasive histology for diagnosis of disease and tracking the effects of new therapies in animal models of neurological disease and, eventually, human subjects. Research techniques being developed will combine multiple coregistered techniques combined with molecular and histological analyses to provide sensitive and specific characterization of the gamut of combined neuroimaging methods for diagnosis and monitoring of neurological diseases.

Review Questions/Problems

1. Diffusion weighted images become positive in acute stroke in:

- a. 16 h
- b. minutes
- c. 8 h
- d. 1 day

2. Advantages of diffusion tensor imaging include:

- a. demonstrates abnormalities when conventional MRI is normal.
- b. provides functional maps of brain activity.
- c. it is indispensable for planning stroke therapy.
- d. can be used to calculate perfusion metrics.

3. Perfusion imaging data can be used to create maps that:

- a. allow for “virtual dissection” of white matter tracts.
- b. are used for creating MR angiograms.
- c. can be utilized to determine tissue at risk for damage in patients with stroke.
- d. show peaks of lactate in tissue damaged by stroke.

4. Magnetic resonance spectroscopic imaging (MRSI) does *not*:

- a. help define the spatial heterogeneity of brain lesions.
- b. provide less useful information than single voxel spectroscopy for distinguishing radiation necrosis versus recurrent tumor.
- c. allow for accurate diagnosis of brain lesions.
- d. demonstrate the same metabolic peaks as single voxel spectroscopy.

5. Computed tomographic brain imaging:

- a. continues to have great utility when evaluating trauma patients.
- b. demonstrates acute hemorrhages as hypodense.

- c. has replaced MRI for many imaging applications.
- d. provides better metabolic information than PET or SPECT.

6. Computed tomographic perfusion imaging:

- a. has already been utilized in major stroke treatment studies.
- b. can be utilized to evaluate brain diffusion.
- c. has limited utility for evaluating stroke patients.
- d. allows multiple parameters such as cerebral blood volume and mean transit time to be calculated.

7. When evaluating seizure patients CT is particularly useful for:

- a. demonstrating the periventricular calcifications of tuberous sclerosis.
- b. demonstrating small soft tissue cortical lesions not detected by MRI.
- c. demonstrating the cortical tubers in patients with tuberous sclerosis.
- d. demonstrating the brainstem calcifications of Sturge-Weber syndrome.

8. SPECT imaging of the brain:

- a. is more expensive than PET imaging.
- b. has been nearly replaced with PET imaging.
- c. availability is a major problem in the United States.
- d. is very useful for evaluating brain perfusion.

9. SPECT imaging does not have:

- a. many radiotracers that can be utilized.
- b. many brain perfusion applications.
- c. the ability to analyze brain tumors with Thallium-201.
- d. undisputed ability to evaluate for lymphoma in patients with human immunodeficiency virus.

10. PET imaging:

- a. has fewer radiotracers that can be utilized than SPECT.
- b. has few imaging applications for which FDG is used.
- c. has the ability to differentiate tumor necrosis from tumor recurrence.
- d. lacks clear ability to differentiate Alzheimer's disease from mild cognitive impairment.

11. Which of these statements is true:

- a. T2-weighted images become positive in a stroke at around 24 h.
- b. Diffusion images allow for an estimation of the mean transit time.
- c. MR spectroscopy utilizes radiotracers.
- d. CTA is used to screen for cerebral aneurysms.

12. MR spectroscopy does *not*:

- a. demonstrate increased myo-inositol in high grade astrocytomas.
- b. potentially only demonstrates subtle findings for gliomatosis cerebri.

- c. demonstrate increased myo-inositol in low grade astrocytomas.
- d. show glutamate and glutamine elevations in low-grade oligodendrogliomas.

Glossary

Δ^9 THC: tetrahydrocannabinol is the major psychoactive ingredient in the Cannabis plant. Δ^9 THC is responsible for both the psychiatric and therapeutic effects obtained from marijuana. Its receptor, the cannabinoid receptor, is located mainly at the presynaptic gap. The areas of the brain most affected are the basal ganglia, cerebellum, cerebral cortex, and the hippocampus. The acute effects consist of degradation in short term memory, changes in sensory perception, reduced concentration, disturbances in motor abilities, hypothermia, increased blood pressure and heart rate, and reduced pain perception.

6-Hydroxydopamine: a neurotransmitter analogue that depletes noradrenergic stores in nerve endings and reduces dopamine levels in brain. Its mechanism of action is linked to cytolytic free-radical production.

A

ACAID: Anterior chamber-associated immune deviation—a unique form of immune tolerance. ACAID is a selective, systemic immune deficiency where Antigen-specific delayed hypersensitivity and complement-fixing antibody responses are impaired by lymphocyte responses while other immune effectors are left preserved.

Ach: Acetylcholine is the chemical responsible for transmitting impulses between neurons in the central and peripheral (parasympathetic and somatic) nervous systems. It is the chemical that allows nerve cells to communicate with one another.

acetylcholinesterase: the enzyme responsible for the destruction of acetylcholine at the synaptic cleft (region between nerve cells) after its neuronal release during neurotransmission.

action potential: Is a spike of electrical discharge that is propagated along the cell membrane. It is essential for information transmission amongst and from nerve cells to tissues throughout the body.

active transport: movement of materials across cell membranes and epithelial layers against an electrochemical gradient, requiring the expenditure of metabolic energy. The process involves the use of cellular energy and commonly ATP to actively pump substances into or out of the cell.

active vaccination: the process of injecting a protein (an antigen) into a host, usually together with an adjuvant (a molecule to enhance immunity) for the purpose of preventing disease. In response, the host immune system generates an immune response that includes specific cells and antibodies against the antigen. Although most commonly used to prevent microbial infections, active vaccination has been used to ameliorate disease.

active zone: specialized region of the cortical cytoplasm of the presynaptic nerve terminal that faces the synaptic cleft. It is the place for synaptic vesicle docking and neurotransmitter release.

ADEM: acute disseminated encephalomyelitis is an immune mediated disease of brain. It is brief but significant and results in direct myelin damage. It usually occurs following a viral infection or vaccination (commonly for measles, mumps or rubella), but it may also appear spontaneously.

acute flaccid paralysis: loss of voluntary motion, due to temporary or permanent dysfunction of lower motor neurons or associated nerve fibers, neuromuscular junction, or muscle fibers. It is the most common sign of acute polio but is also associated with West Nile Virus infection. In chronic cases of permanent flaccid paralysis muscle tone is decreased and muscle atrophy may occur.

adaptive immune system: the adaptive immune system evolved in early vertebrates and allows for a specific and targeted response based upon immunological memory of antigens or related antigens previously encountered by the host innate immune systems. This requires the recognition of specific “non-self” antigens. The effectors of the adaptive immune response include T cells and B cells.

adenoviruses: these are a family of non-enveloped medium-sized (90–100 nm), icosahedral double-stranded DNA viruses that infect various mammalian species, including humans. These viruses commonly cause mild respiratory infections. Adenovirus-based vectors have been used for gene delivery into the nervous system, as high vector titers can be generated, and these episomally maintained vectors efficiently infect and express transgenes in a variety of cell types including the non-dividing cells.

AAV: adeno-associated virus is a non-pathogenic member of the parvovirus family that harbors a single-stranded DNA viral genome. Vectors derived from AAV can carry up to a 4.5-kb transgene and stably express a transgene *in vivo* months to several years.

adjunctive: something joined or added to another thing but not essentially a part of it, used in this context to refer to additional therapies for HIV-related neurological conditions.

adjuvant: a formulation of substances that is used to enhance/potentiate immune response to an antigen. Complete adjuvants are water in oil emulsions composed of inactivated or killed mycobacteria—usually *Mycobacterium tuberculosis*. Whereas incomplete adjuvants are the same adjuvants, but without the mycobacterial components.

(adsorptive) endocytosis: cellular uptake of extracellular materials within membrane-limited vacuoles or microvesicles. ENDOSOMES play a central role in endocytosis.

ACTH: adrenocorticotrophic hormone is a peptide hormone released by anterior pituitary cells in response to stressful stimuli that causes the synthesis and release of cortisol (corticosteroid) from the adrenal cortex. It is an important component of the hypothalamic-pituitary-adrenal (HPA) axis. ACTH is released from pro-opiomelanocortin and secreted from corticotropes in response to corticotropin-releasing hormone (CRH) released by the hypothalamus.

(Adsorptive) transcytosis: a mechanism for transcellular transport in which a cell encloses extracellular material in an invagination of the cell membrane to form a vesicle, then moves the vesicle across the cell to eject the material through the opposite cell membrane by the reverse process.

adult stem cell: a cell found in adult somatic tissue that can differentiate into the cells of the particular tissue in which it resides and can self-renew while maintaining its differential capability.

AIDS: Acquired Immunodeficiency Syndrome (AIDS) is an acquired defect of cellular immunity associated with infection by the human immunodeficiency virus (HIV), a CD4-positive T-lymphocyte count under 200 cells/ μ L or less than 14% of total lymphocytes, and increased susceptibility to opportunistic infections and malignant neoplasms. Clinical manifestations also include emaciation (wasting) and demen-

tia. These elements reflect criteria for AIDS as defined by the CDC in 1993.

Akt: serine/threonine protein kinase that is a cellular homologue of the viral oncogene v-Akt. There are three genes in the Akt family: Akt1, Akt2, and Akt3. Akt1 is involved in cell survival pathways by inhibiting apoptosis. Akt2 is an important signaling molecule in the Insulin signaling pathway, and is required to induce insulin transport. The role of Akt3 is unknown, but it is predominately expressed in the brain.

alkylosing spondylitis: literally “stiff vertebra” is an autoimmune inflammatory disease that primarily affects the intervertebral joints (joints of the spine) and the sacro-iliac joint.

allele: the name given to a specific polymorphic variation.

allele association: association with a specific allele but not necessarily a genotype.

allograft: tissue transplanted from the same species but of a different genotype.

alpha adrenergic receptor: one of two general classes of G protein-coupled receptors that can be further sub-classified and responds to the neurotransmitter norepinephrine.

α -MSH: alpha melanocyte stimulating hormone is a tripeptide derived from proopiomelanocortin that stimulates production of melanin and acts on melanocortin-1 receptors found on immune cells.

alpha synuclein: an abundant presynaptic neuronal protein found in the brain of uncertain function, but thought to act as a molecular chaperone involved in vesicular transport. Mutation and/or oxidation of alpha-synuclein increase its propensity to aggregate and is a major component of Lewy bodies that plays a role in neurodegeneration and neuroprotection.

AD: Alzheimer’s disease is the most common degenerative brain disease of unknown cause resulting in progressive mental deterioration with disorientation, memory disturbance and confusion. AD leads to progressive dementia, often accompanied by dysphasia and/or dyspraxia. The condition may also give rise ultimately to spastic weakness and paralysis of the limbs, epilepsy and other variable neurological signs. Alzheimer disease is marked histologically by the degeneration of brain neurons especially in the cerebral cortex and by the presence of neurofibrillary tangles and plaques comprised of highly insoluble β -amyloid peptides in the CNS.

amacrine cell: lateral inhibitory interneuron in the inner retina located at the inner plexiform layer where bipolar cells and ganglion cells synapse. Amacrine cells deliver the majority of the ganglion cells input, and also regulate the output of the cone bipolar cells. These cells are thus responsible for the complex processing of the retinal image by adjusting brightness as well as detecting motion.

amphetamine: a central nervous stimulant that increases neuronal activity by releasing norepinephrine, dopamine and/or serotonin from nerve endings.

amygdala: an almond-shaped mass of gray matter, one in each hemisphere of the brain, associated with feelings of fear and aggression and important for visual learning and memory.

A β : Amyloid-beta is a peptide of 39–43 amino acids that is the main constituent of amyloid plaques in the brains of Alzheimer's disease patients. Similar plaques appear in some variants of Lewy body dementia and in inclusion body myositis, a muscle disease. A β also forms aggregates coating cerebral blood vessels in cerebral amyloid angiopathy.

APP: amyloid precursor protein is a single transmembrane molecule, a causative gene of FAD, and is acted upon by proteases to form the amyloid- β peptide.

ALS: Amyotrophic lateral sclerosis is a rare fatal progressive degenerative disease of unknown cause that affects motor neurons, usually begins in middle age, and is characterized by muscular weakness; called also Lou Gehrig's disease.

amyloid: an abnormal aggregation of proteins or protein fragments with a beta-pleated sheet secondary structure.

animal models: normal animals modified mechanically, genetically or chemically to create laboratory paradigms with infrahuman species (usually rodents) which study behavior, neurochemistry, or physiology to demonstrate all or part of the characteristics of a disease.

antibodies repertoire: antibody genes are pieced together from widely scattered bits of DNA. The possible combinations are nearly endless. As this gene forms, it assembles segments that will determine the variable-V, diversity-D, joining-J, and constant-C segments of this antibody molecule. For example, variable-region and joining-region rearrangements of the immunoglobulin light chain called V_LJ_L rearrangements.

antibody titer: the concentration of a specific antibody in blood.

antidepressant drugs: pharmacological agents used for ameliorating symptoms of depressive disorders, including monoamine oxidase inhibitors, selective serotonin reuptake inhibitors, serotonin/norepinephrine reuptake inhibitors, and other agents.

anti-ganglioside antibodies: circulating autoantibodies directed against gangliosides. Anti-ganglioside antibodies are associated with axonal forms of GBS and can be induced experimentally in laboratory animals.

antigen presenting cells (APC): a cell that displays foreign antigens complexed with MHC on its surface. T-cells may recognize this complex using their T-cell receptor (TCR).

antigen: the molecule against which an immune response is raised.

anti-inflammatory cytokines: a series of immunoregulatory molecules that suppress proinflammatory responses.

antipsychotic drugs: pharmacological agents used to treat psychotic disorders, including schizophrenia, mania, and psychotic depression. These drugs are usually classified as "typical" or "atypical," depending on their affinity for the dopamine D₂ receptor, lack of extrapyramidal side effects, and action upon serotonin receptors.

antiretroviral therapy: use of anti-HIV agents to treat disease by lowering viral titer and reducing viral replication, usually in combination of at least three drugs.

antithymocyte globulin: purified gamma globulin from the serum of rabbits immunized with human thymocytes. It is used for induction of immunosuppression in the treatment of acute renal transplant rejection.

apoE: apolipoprotein E is a component of lipoprotein complex both in plasma and cerebrospinal fluid, responsible for cholesterol transport in the blood stream. One copy of the ApoE4 allele is an established risk factor of AD.

apoptosis: a genetically determined process resulting in cell self-destruction that is marked by the fragmentation of nuclear DNA, and is a normal physiological process eliminating DNA-damaged, superfluous, or unwanted cells (as immune cells targeted against the self in the development of self-tolerance). Apoptosis may occur prematurely in neurodegenerative conditions; also called programmed cell death.

arbor: dendritic arbor, a single dendrite, the arbor density is called arborization.

association: describes a relationship between a disease and a specific allele or haplotype of a polymorphism.

astrocytes: major glial cells in the CNS (star-shaped cell as of the neuroglia). Astrocytes are characterized by histopathologically by glial fibrillary associated protein (GFAP). Astrocytes perform many functions including formation of the blood brain barrier, provide neurotrophic factors and metabolic support to the CNS, and have a role both in the repair and scarring process in the brain.

atropine: an alkaloid isolated from the belladonna plant that blocks the action of acetylcholine on muscarinic cholinergic receptors.

autonomic nervous system: the portion of the peripheral nervous system which acts autonomously through either of two divisions (parasympathetic and sympathetic) and regulates the action of smooth muscle, exocrine glands and the heart.

axon: the long extension of a neuron that carries nerve impulses away from the cell body.

axonal transport: bidirectional transport process, consisting of anterograde (transport of presynaptic molecules) and retrograde transport systems (neurotrophic signaling).

axon terminals: the hair-like ends of the axon.

atherosclerosis: characterized by the formation of plaques within the innermost layer of artery walls and narrowing of the vessel lumen. Vascular occlusion in the brain leads to stroke and in the coronary arteries leads to heart attack.

autoantibodies: immunoglobulins directed against self-antigens, representing an autoimmune process.

autoimmune disease: a condition in which a person's immune cells recognize self-produced molecules (self-antigens), leading to the inappropriate destruction of host tissue, e.g. rheumatoid arthritis, multiple sclerosis, and possibly Addison's disease.

autoimmune T cells: T cells that recognize self-antigens and are responsible for cell-mediated destruction of host tissue in an autoimmune disease.

autoimmunity: a condition in which an individual's immune system reacts against his or her own tissues, causing diseases such as lupus erythematosus.

axonal damage: via inflammation not only the myelin sheath, but also the axon itself is destroyed.

B

Bad: a pro-apoptotic member of the Bcl-2 gene family involved in initiating apoptosis. BAD-Bcl-2-associated death promoter protein.

β -amyloid peptide (A β): a principal component of senile plaque, a pathological hallmark of AD, which is generated by β and γ -processing of APP.

barbiturates: a group of sedative-hypnotic agents that also have anti-anxiety effects. Barbiturates act on GABA-A receptors.

basiliximab: humanized monoclonal antibody directed against the IL-2 receptor on T cells. It is used for the prophylaxis of acute organ rejection in adult patients.

Bax: a protein of the Bcl-2 gene family that promotes apoptosis by competing with Bcl-2.

Bcl2: the prototype for a family of mammalian proteins located in the membranes of the endoplasmic reticulum (ER), nuclear envelope, and in the outer membranes of the mitochondria. They can be either pro-apoptotic (Bax, BAD, Bak and Bok among others) or anti-apoptotic.

BCR: B cell receptor is an antigen-specific receptor is a sample of the antibody it is prepared to manufacture; it recognizes antigen in its natural state.

Bcl11a: C2H2 type zinc-finger protein. The corresponding mouse gene is a common site of retroviral integration in

myeloid leukemia, and may function as a leukemia disease gene, in part, through its interaction with BCL6. During hematopoietic cell differentiation, this gene is down-regulated. It is possibly involved in lymphoma pathogenesis since translocations associated with B-cell malignancies also deregulate its expression.

BDNF: brain derived neurotrophic factor is a member of the nerve growth factor family of trophic factors. In the brain, BDNF has a trophic action on retinal, cholinergic, and dopaminergic neurons, and in the peripheral nervous system it acts on both motor and sensory neurons. (From Kendrew, The Encyclopedia of Molecular Biology, 1994).

belladonna alkaloid: any of several compounds that block the effect of acetylcholine on muscarinic cholinergic receptors.

benzodiazepines: a group of anti-anxiety agents that can also produce sedation, hypnosis and that have anti-convulsant effects. In the CNS, benzodiazepines act on GABA-A receptors. They also act on peripheral benzodiazepine receptors in the immune system.

beta-amyloid precursor protein converting enzyme (BACE): a single transmembrane aspartic proteinase, which processes APP at β -site; the β -secretase.

beta adrenergic receptor: one of two general classes of G protein-coupled receptors that can be further sub-classified and responds to the neurotransmitter norepinephrine.

beta-pleated sheet: a molecular structure where proteins spontaneously fold into a layered shape, analogous to the accordion folds of a fan.

bethanechol: a derivative of acetylcholine with stimulant effects primarily on the smooth muscle of the gastrointestinal tract and the urinary bladder.

bipolar cell: retinal interneuron that transfers visual information from photoreceptors to ganglion cells.

biogenic amine hypothesis: the hypothesis that major depressive disorder and bipolar disorder are functionally related to abnormal levels of catecholamines and/or serotonin.

Bioinformatics: field of science in which biology and computer science merge into a single discipline to create, manage and interpret massive sets of complex biological data.

Biomarker: distinctive biological indicator of biological state, process or condition.

bipolar disorder: a mental disorder characterized by cyclic episodes of mania or hypomania, usually accompanied by depressive episodes.

block copolymer: a polymer in which all of one type of monomer are grouped together, and all of the other type are grouped together. A block copolymer can be thought of as two homopolymers joined together at the ends.

block ionomer complex: a complex between two oppositely charged block copolymers.

blood-brain barrier: specialized non-fenestrated tightly-joined ENDOTHELIAL CELLS with TIGHT JUNCTIONS that form a transport barrier for certain substances between the cerebral capillaries and the BRAIN tissue.

BLIMP1: a protein that acts as a repressor of beta-interferon gene expression. The protein binds specifically to the PRDI (positive regulatory domain I element) of the β -IFN gene promoter. Transcription of this gene increases upon virus induction.

botulinum toxin: a group of zinc proteases that can degrade one or more of the key proteins required for the process of exocytosis thus preventing the neuronal release of acetylcholine.

brain: the part of the central nervous system contained within the cranium, comprising the prosencephalon, mesencephalon, and rhombencephalon. It is derived from the anterior part of the embryonic neural tube.

brain endothelial cell: highly specialized cells that form the blood-brain barrier.

butoxamine: an antagonist of norepinephrine action selective for the subtype two beta adrenergic receptor.

C

C5a: the 74-residue anaphylatoxin derived from C5 during complement activation that possesses inflammatory and immune stimulatory properties causing the accumulation of white blood cells at the site of complement activation.

C5a agonist: a peptide mimetic of natural C5a that exhibits certain C5a-like activities.

Ca²⁺ signaling: signal transduction mechanism in which Ca²⁺ is recruited from extracellular or intracellular stores to the cytoplasm in response to external stimuli. Elevation of intracellular Ca²⁺ activates a series of enzymes.

CAG repeats: primary determinant of the onset of HD and other neurodegenerative disorders, including SBMA, DRPLA, SCA 1–3, 6, 7 and 17. CAG codes for the amino acid Glutamine, and extra repeats is thought to lead to a “toxic gain of function,” and increased propensity of the translated protein to form aggregates. Genetic testing of the HD CAG repeat is a useful tool for clinical diagnosis.

calcium excitability: refers to the dynamics of calcium homeostasis.

cAMP signaling: signal transduction cascade initiated by the action of external stimuli on binding to a G-protein couple receptor (Gs) resulting in activation of adenylyl cyclase, production of cyclic AMP and activation of cyclic AMP-dependent protein kinase.

***Campylobacter jejuni*:** Gram-negative bacterium, which is one of the most frequent causes of bacterial gastroenteritis world-wide. *Campylobacter jejuni* gastroenteritis is the most frequently recognized preceding infection in GBS.

cannabinoids: substances that bind to cannabinoid receptors.

case-control: study describes an association study that compares allele frequencies using unrelated affected cases and matched controls.

caspase: known as proteases, which play essential roles in apoptosis (cell death) and inflammation.

CD1d: the sole group-2 member of the CD1 family of major histocompatibility (MHC)-like glycoproteins.

CD3: complex of delta, epsilon, gamma, zeta and eta chains of integral membrane glycoproteins that associates with T cell antigen receptor (TCR), and is required for TCR cell surface expression and signal transduction. CD3 is a universally expressed by T cells. Member of immunoglobulin superfamily.

CD4: nonpolymorphous glycoproteins belonging to immunoglobulin superfamily. Expressed on surface of T helper cells, accessory cells, macrophages and serves as co-receptor in MHC class II-restricted antigen induced T cell activation. Major receptor for HIV-1.

CD5: belongs to ancient scavenger receptor superfamily. CD5+ B cells, which may arise from B-1 cells (subset of B cells) produce “generalist antibodies”—polyreactive low affinity “natural” antibodies to exogenous antigens (tetanus toxoid, lipopolysaccharide) as well as autoreactive antibodies. CD5 may serve as a dual receptor, giving either stimulatory or inhibitory signals depending both on the cell type and the development stage. Key regulator of immune tolerance; abnormalities may produce autoimmunity.

CD8: cell surface glycoprotein, member of immunoglobulin superfamily. Heterodimer of an alpha and a beta chain linked by two disulfide bonds; heterodimer on thymocytes and homodimer on peripheral blood T cells MHC class I restricted receptor; binds to nonpolymorphic region of class I molecules; may increase avidity of interactions between cytotoxic T cell and target cell during antigen-specific activation. Can kill target cells by recognizing peptide-MHC complexes on them or by secreting cytokines capable of signaling through death receptors on target cell surface. CD8 alpha cells promote survival and differentiation of activated T cells into memory CD8+ T cells, which may become clonal (but not malignant) in the elderly.

CD11b: member of integrin receptor family; also called integrin alpha M, Mac-1. Mediates adhesion to substrates by opsonization with iC3b and subsequent phagocytosis, neutrophil aggregation, and chemotaxis. Ligands include fibrinogen,

Factor X, ICAM1, iC3b, some bacteria. CD11b is a marker for both macrophages and microglia, and expression increases with cell-activation.

CD11c: member of β_2 of integrin receptor family; also called integrin α_X , CR4, LeuM5. Clears opsonized particles and immune complexes; also binds to fibrinogen and is involved in adhesion of monocytes and neutrophils to endothelium. Myeloid cell marker.

CD19: response regulator that plays a dominant role in establishing signaling thresholds for antigen receptors and other surface receptors on B cells; also regulates B cell development, activation and differentiation. Assembles with the antigen receptor of B lymphocytes in order to decrease the threshold for antigen receptor-dependent stimulation. Co-receptor with CD21. Earliest B cell antigen in fetal tissue. B cell marker.

CD21: complement component receptor-2 (CR2) that binds to C3d.

CD25: IL-2 receptor α chain; exists in at least three forms. Limited expression may safeguard against catastrophic T-cell proliferation by immunogenic stimulus. Expressed, typically at high levels, on PHA-stimulated T cells, and is commonly used as a marker for activated T cells. Expressed on B cells stimulated with anti-IgM antibody. Expressed on monocytes/macrophages stimulated with LPS. Full signaling of IL-2 requires trimer with CD122 (IL-2R β) and CD132 (IL-2R γ) chains.

CD27: marker of T cell activation. CD27/CD70 interactions also regulate B cell proliferation and T cell differentiation. The protein is a member of the TNF-receptor superfamily. This receptor is required for generation and long-term maintenance of T cell immunity. It binds to ligand CD70, and plays a key role in regulating B-cell activation and immunoglobulin synthesis. This receptor transduces signals that lead to the activation of NF- κ B and MAPK8/JNK. Adaptor proteins TRAF2 and TRAF5 have been shown to mediate the signaling process of this receptor. CD27-binding protein (SIVA), a pro-apoptotic protein, can bind to this receptor and is thought to play an important role in the apoptosis induced by this receptor.

CD28: cell adhesion molecule; co-receptor for B cell-T cell cooperation. Promotes T cell activation. Receptor for CD80 (B7.1) & CD86 (B7.2), found on activated B cells. Constitutive, high abundance, low affinity receptor; opposite signals are mediated by CTLA4 (CD152). Result of T cell antigen stimulation depends on sum of effects of T cell receptor, CD28 and its ligand, CTLA4 and its ligand. CD8+, CD28+ T cells mediate antigen specific cytotoxic T cells (class I restricted) (90% of CD8+ T cells). CD8+, CD28- T cells mediate suppressor T cells (10% of CD8+ T cells). CD28 costimulation is essential for CD4-positive T-cell proliferation, survival, interleukin-2 production, and T-helper type-2 (Th2) development.

CD30: tumor necrosis factor receptor superfamily, member 8, is a member of the TNF-receptor superfamily. This receptor is expressed by activated, but not by resting, T and B cells. TRAF2 and TRAF5 can interact with this receptor, and mediate the signal transduction that leads to the activation of NF- κ B. This receptor is a positive regulator of apoptosis, and also has been shown to limit the proliferative potential of autoreactive CD8 effector T cells and protect the body against autoimmunity. Two alternatively spliced transcript variants of this gene encoding distinct isoforms have been reported.

CD34: cell-cell adhesion molecule and cell surface glycoprotein. May mediate attachment of stem cells to bone marrow extracellular matrix or directly to stromal cells. Constitutively expressed on endothelial cells.

CD38: a multifunctional ectoenzyme widely expressed in cells and tissues especially in leukocytes and endothelial cells. CD38 also functions in cell adhesion, signal transduction and calcium signaling. Positive and negative regulator of cell activation and proliferation, depending on the cellular environment.

CD40: member of the TNF-receptor superfamily. This receptor has been found to be essential in mediating a broad variety of immune and inflammatory responses including T cell-dependent immunoglobulin class switching, memory B cell development, and germinal center formation. AT-hook transcription factor AKNA is reported to coordinately regulate the expression of this receptor and its ligand, which may be important for homotypic cell interactions. Adaptor protein TNFR2 interacts with this receptor and serves as a mediator of the signal transduction. The interaction of this receptor and its ligand is found to be necessary for amyloid-beta-induced microglial activation, and thus is thought to be an early event in Alzheimer disease pathogenesis. Two alternatively spliced transcript variants of this gene encoding distinct isoforms have been reported.

CD44: family of cell surface glycoproteins with isoforms generated by alternate splicing of mRNA. CD44 is important in epithelial cell adhesion (cell-cell and cell-matrix) to hyaluronate in basement membranes and in maintaining polar orientation of cells; also binds laminin, collagen, osteopontin, matrix metalloproteinases (MMPs) and fibronectin. Involved in leukocyte attachment and rolling on endothelial cells, homing to peripheral lymphoid organs and sites of inflammation and leukocyte aggregation, hematopoiesis, and tumor metastasis.

CD45: leukocyte common antigen (LCA); a protein tyrosine phosphatase. Critical requirement for T and B cell antigen receptor-mediated activation. Expressed on all hematopoietic cells except erythrocytes and platelets at different levels. Some isoforms of CD45 are CD45RO, CD45RA, and CD45RB. Each CD45 isoform is distinguished from one another depending on the type of exon the CD45 has or the exons the CD45 does

not have. The CD45RA isoform contains the A exon only and the CD45RB has the B exon only whereas the CD45RO has neither the none of the exons: A, B, or C.

CD45RA: CD45RA—expressed by naive/resting T cells, medullary thymocytes

CD45RO: CD45RO—expressed by memory/activated T cells, cortical thymocytes

CD56: N-CAM (neuronal adhesion molecule). Regulates homophilic (like-like) interactions between neurons and between neurons and muscle. Also associates with fibroblast growth factor receptor and stimulates tyrosine kinase activity of receptor to induce neurite outgrowth. When neural crest cells stop making N-CAM and N-cadherin and start displaying integrin receptors, cells separate and migrate. Contributes to cell-cell or cell-matrix adhesion during development. Lymphocyte activated killer phenomenon mediated by IL-2 activated CD56+, CD3-, NK cells. Prototypic marker of NK cells, also present on subsets of CD4+ and CD8+ T cells.

CD62L: L selectin; LECAM-1. Mediates lymphocyte homing to high endothelial venules of peripheral lymphoid tissue, leukocyte rolling on activated endothelium at inflammatory sites.

CD64: high affinity receptor binds to Fc region of IgG. CD64 is important in phagocytosis via receptor-mediated endocytosis of IgG-antigen complexes. Mediates antigen capture for presentation to T cells, antibody-dependent cellular cytotoxicity, release of cytokines and reactive oxygen intermediates.

CD68: a 110-kDa transmembrane glycoprotein that is highly expressed by human monocytes and tissue macrophages. It is a type I integral membrane protein with a heavily glycosylated extracellular domain. May have a role in macrophage phagocytic activities. Specific to lysosomes, not cell lineage. Expressed by macrophage/monocytes, basophils, dendritic cells, mast cells, myeloid cells, CD34+ progenitor cells, neutrophils, osteoclasts, activated platelets, B and T cells.

CD117 (c-Kit): the tyrosine kinase type receptor. The c-Kit gene encodes a 145-kDa transmembrane protein that is a member of the receptor tyrosine kinase subclass III family that includes platelet-derived growth factor receptor (PDGF-R), macrophage colony-stimulating factor receptor (M-CSF-R or c-fms), and fms-like tyrosine kinase-3/fetal liver kinase-2 (Flt-3/Flt-2). The ligand for c-Kit, Steel factor (SF) or kit ligand, stem cell factor, and mast cell growth factor, exists both as a secreted and membrane-bound form where the latter appears to be most important for biologic activity *in vivo*. Important for development and survival of mast cells, hemopoietic stem cells, melanocytes, germ cells, and interstitial cells of Cajal.

CD122: IL-2 receptor beta chain.

CD123: interleukin 3 receptor, alpha (low affinity). The receptor is comprised of a ligand specific alpha subunit and a signal transducing beta subunit shared by the receptors for

interleukin 3 (IL-3), colony stimulating factor 2 (CSF2/GM-CSF), and interleukin 5 (IL-5). The binding of this protein to IL-3 depends on the beta subunit. The beta subunit is activated by the ligand binding, and is required for the biological activities of IL-3.

CD134 (OX40): tumor necrosis factor receptor superfamily, member 4. This receptor has been shown to activate NF-kappaB through its interaction with adaptor proteins TRAF2 and TRAF5. Knockout studies in mice suggest that this receptor promotes the expression of apoptosis inhibitors BCL2 and BCL2L1/BCL2-XL, and thus suppresses apoptosis. The knockout studies also suggest the roles of this receptor in CD4+ T cell response, as well as in T cell-dependent B cell proliferation and differentiation.

CD154: CD40 ligand (TNF superfamily, member 5, hyper-IgM syndrome) is expressed on the surface of T cells. It regulates B cell function by engaging CD40 on the B cell surface. A defect in this gene results in an inability to undergo immunoglobulin class switch and is associated with hyper-IgM syndrome.

CD278: inducible T-cell co-stimulator, belongs to the CD28 and CTLA-4 cell-surface receptor family. It forms homodimers and plays an important role in cell-cell signaling, immune responses, and regulation of cell proliferation.

cell body: the body of the neuron containing the nucleus (also called the soma or perikaryon).

cell-mediated delivery: delivery of therapeutic agents to the site of action inside carrier cells.

central memory t cells: Memory T cells that express L-selectin and CC-chemokine receptor 7 (CCR7) and have the capacity to circulate from the blood to the secondary lymphoid organs. They have a nonpolarized differentiation state in that they secrete IL-2 but not IFN- γ or IL-4; however, on restimulation, they rapidly differentiate into cytokine-producing effector cells.

central nervous system (CNS): The main information-processing organs of the nervous system, consisting of the brain, spinal cord, and meninges that controls and coordinates most function of the body and mind.

centroblast: a proliferating germinal-center B cell, which undergoes somatic hypermutation and immunoglobulin class switching.

centrocyte: the non-dividing progeny of a centroblast. These cells need to be selected on the basis of affinity for antigen, following interaction with immune complexes that are associated with follicular dendritic cells, and ability to elicit help from follicular B helper T (T_{FH}) cells.

ceramide: a sphingosine-based lipid molecule that regulates a wide spectrum of biological processes such as cellular differentiation, proliferation, apoptosis and senescence.

CSF: cerebrospinal fluids are fluid in the ventricles of the brain, between the arachnoid and pia mater, and surrounding the spinal cord that absorbs shocks and maintains uniform pressure.

cerebral amyloid angiopathy: the deposition of β -amyloid in brain blood vessels.

chemoattractant-receptor homologous molecule expressed by t_H2 cells (crth2): A cell-surface marker for human T helper 2 cells.

chemokines: a group of secreted proteins within the family of cytokines that by definition relate to the induction of migration. These “chemotactic cytokines” are produced by and target a wide variety of cells, but primarily address leukocyte chemoattraction and trafficking of immune cells to locations throughout the body via a concentration-dependent gradient. Chemokines are categorized on the basis of the protein structure according to the types of cysteine motifs (e.g., C–C, C–X–C)

chemotaxis: attraction and trafficking of cells to locations via a gradient.

choline acetyltransferase: the enzyme present in nerve endings that is responsible for the esterification of choline yielding the neurotransmitter acetylcholine.

cholinergic receptors: one of two general classes of receptors (either G protein-coupled or ligand-gated) that can be further sub-classified and responds to the neurotransmitter acetylcholine.

chorea: an abnormal voluntary movement disorder, and sub-category of dyskinesias, which are caused by overactivity of the neurotransmitter dopamine in the areas of the brain that control movement. Chorea is a primary feature of HD and important diagnostic symptom.

chromogranin A: a type of chromogranin which was first isolated from chromaffin cells of the adrenal medulla but is also found in other tissues and in many species including human, bovine, rat, mouse, and others. It is an acidic protein with 431 to 445 amino acid residues. It contains fragments that inhibit vasoconstriction or release of hormones and neurotransmitter, while other fragments exert antimicrobial actions.

chronic inflammatory neuropathy: a chronic autoimmune neuritis, which involves demyelination of peripheral nerves and spinal roots. This disease is thought to be mediated by autoantibody production to peripheral myelin. The effector cell types include macrophages, B cells, and CD4+ T cells.

choroid: a layer of the eye adjacent to the RPE containing a dense bed of fenestrated capillaries (also called the choriocapillaris).

clade: a group of biological taxa (as species) that includes all descendants of one common ancestor.

class-switch recombination: the process by which proliferating B cells rearrange their DNA to switch from expressing IgM (or another class of immunoglobulin) to expressing a different immunoglobulin heavy-chain constant region, thereby producing antibody with different effector functions.

clinical trials: an experiment to test quality, value, or usefulness of a therapeutic agent in human subjects.

CNPase: refers to 2',3'-cyclic nucleotide 3'-phosphodiesterase that is present in myelin.

CNS homeostasis: level of maintenance needed for normal central nervous system health and function.

combination therapy: the use of two or more therapies, especially drugs, to treat a disease or condition.

cocaine: a compound present in the leaves of coca trees that is a central nervous stimulant, which increases neuronal activity by lengthening the duration of action of norepinephrine, dopamine and/or serotonin in the neuronal synapse.

complement system: a host defense mechanism made up of a group of serum proteins involved in the control of inflammation, the activation of humoral and acquired immune responses, and the lytic attack on cell membranes.

complex disease: is a disease due to the interaction of multiple susceptibility genes and/or environmental risk factors. Most common medical problems fall within this category

cone: photo-sensitive retinal cell mediating color vision and responsive to higher light levels than rods.

connexins (Cx): connexins, or gap junction proteins, are a family of structurally-related transmembrane proteins that assemble to form vertebrate gap junctions.

corticosteroids: a group of natural and synthetic hormones that are immunosuppressive agents and are used for treatment of transplant rejection and autoimmune disorders. Natural corticosteroids are synthesized from cholesterol in the adrenal cortex and are involved in the stress response and regulation of inflammation, carbohydrate metabolism, protein catabolism, blood electrolyte levels, and behavior. Corticosteroids are further classified as glucocorticoids and mineralocorticoids.

CRH: corticotropin releasing hormone is a peptide hormone produced by cells in the hypothalamus in response to stressful stimuli that causes the synthesis and release of ACTH from anterior pituitary cells.

Creutzfeldt-Jakob disease (CJD): the most common prion disease of humans and can have a sporadic, familial or acquired etiology.

Crohn's disease: is a chronic autoimmune disease affecting the gastrointestinal tract, and can affect any region from mouth to anus.

CXCR4 receptor: the receptor for the chemokine stromal cell-derived factor (SDF-1).

cyclic nucleotide 3' phosphohydrolase (CNPase): a component of myelin that demonstrates increased activity in active stages of MS:

cyclooxygenase-2 (COX-2): an inducibly-expressed subtype of prostaglandin-endoperoxide synthase. It plays an important role in many cellular processes and inflammation. It is the target of cox2 inhibitors.

cyclophosphamide: a nitrogen mustard alkylating agent that is used as an anticancer agent and immunosuppressive agent mainly in the treatment of autoimmune diseases.

cyclosporine: a cyclic polypeptide that acts as a calcineurin inhibitor. It is an immunosuppressive agent that is used in organ transplantation and autoimmune diseases.

cytokines: regulatory soluble glycoproteins (8–30 kDa), such as interleukins and lymphokines, secreted by inflammatory leukocytes and some non-leukocytic cells that act as intercellular mediators. They differ from classical hormones in that they are produced by a number of tissue or cell types rather than by specialized glands. They generally act locally in a paracrine or autocrine rather than endocrine manner, and facilitate communication among immune system cells and between immune system cells and the rest of the body.

cytotoxic T lymphocytes (CTL): T cells that can kill other cells. Most cytotoxic T cells are MHC class I-restricted CD8+ T cells. Cytotoxic T cells are important in host defense against cytosolic pathogens.

D

daclizumab: humanized monoclonal antibody directed against the IL-2 receptor on T cells. It is used for the prophylaxis of acute organ rejection in adult patients.

delusions: fixed false beliefs

dementia: a term describing memory loss and other cognitive impairments that result from a number of causes, including Alzheimer's disease; marked by the development of multiple cognitive deficits (including memory impairment, aphasia, and inability to plan and initiate complex behavior). Deteriorated mentality is often accompanied by emotional apathy.

demyelination: the act of demyelinating, or the loss of the myelin sheath insulating the nerves, and is the hallmark of some neurodegenerative autoimmune diseases, including: multiple sclerosis, transverse myelitis, chronic inflammatory demyelinating polyneuropathy, Guillain-Barre Syndrome, and adrenoleukodystrophy. When myelin degrades, conduction of signals along the nerve can be impaired or lost, and the nerve eventually withers.

dendrites: the branching structures projecting from the cell body of a neuron that receive messages from other neural cells and work to transmit these messages via electrical impulses to the cell body from which they project.

dendritic spine: a small protrusion from the dendrite comprised of a head that forms one half of a synapse and a thinner neck that connects the head to the dendrite. Responsible for the controlled diffusion of molecules from the synapse to the dendrite. They contain the highest concentrations of actin, which retains dynamic activity and can drive rapid changes in its shape and therefore its function.

dentate granule cell layer: tiny neurons (10 µm in diameter) located in the dentate gyrus of the hippocampus, which contain glutamatergic projection axons, and are one of only two major types of adult neuronal populations to undergo neurogenesis.

dentate gyrus: a subfield in hippocampus.

depression: mood disorder (clinically, major depressive disorder or a milder form referred to as dysthymia) characterized by persistent sadness, hopelessness, cognitive impairment and other symptoms that interfere with work, sleep, etc. and in severe cases can lead to suicide.

dexamethasone suppression test: measures cortisol levels in response to dexamethasone (synthetic cortisol) administration. Specifically, it tests the response of adrenal glands to ACTH (adrenocorticotropic hormone which is secreted from the anterior pituitary gland of the brain). Cortisol levels should decrease following dexamethasone administration. Abnormally high cortisol levels are seen following dexamethasone administration in up to 50% of patients with a major depressive disorder.

differentiation: the ability of a pluripotent cell to become a specialized cell type by expressing distinct lineage specific genes and undergoing morphological changes.

dobutamine: a norepinephrine derivative that mimics norepinephrine action primarily at the subtype one beta adrenergic receptor.

dopamine: one of the catecholamine neurotransmitters in the brain. It is derived from tyrosine and is the precursor to norepinephrine and epinephrine. Dopamine is a major transmitter in the extrapyramidal system of the brain, and important in regulating movement. A family of receptors (receptors, dopamine) mediate its action.

dopamine hypothesis: the hypothesis that schizophrenia is functionally related to excessive dopamine activity. Evidence for this is the observation that many antipsychotics have DA-antagonistic effects.

dopaminergic neurons: neurons that utilize dopamine as a neurotransmitter.

doublecortin: binds to the microtubule cytoskeleton, stabilizing them and causing bundling of microtubules.

drug delivery: the transport of therapeutic agents to the site of action.

d-tubocurarine: an alkaloid that blocks the action of acetylcholine on skeletal muscles causing paralysis

dynorphins: endogenous opioid peptides, 17 amino acids in length, derived from prodynorphin.

dysthymia: minor depression, with fewer and less intense symptoms as major depressive disorder.

E

E2A: immunoglobulin enhancer binding factors, also E12/E47. Binds the immunoglobulin κ chain enhancer and is involved in promoter regulation.

EAE: experimental allergic/autoimmune encephalitis is an animal model for demyelinating diseases, such as multiple sclerosis. It is induced by injection of myelin basic protein or whole CNS tissue together with adjuvants.

EBF: early B-cell factor.

effector memory t cells: cells that have an L-selectin⁻ CCR7 phenotype. They have immediate effector functions, including rapid production of cytokines (IFN- γ or IL-4), and they migrate to sites of inflammation, such as the skin and the gut. They recognize foreign invaders with a faster and stronger immune response than the initial immune response.

embryonic germ cell (EG): a totipotent cell that can differentiate into all the cells of the organism, self-renew while maintaining its differential capability, the precursor for adult germ cells, and can be isolated from primordial germ cells of 5–9-week human fetuses.

embryonic stem cell (ES): a multipotent stem cell that can differentiate into all the cells of the organism except the trophoblast, self-renew while maintaining its differential capability, and is isolated from the inner cell mass of the blastocyst stage embryo.

encephalopathy: a disease of the brain; especially one involving alterations of brain function and/or structure.

endocytosis: uptake of molecules that cannot readily pass through the cell membrane through engulfment by the membrane resulting in the formation of a vesicle. This process is employed for a variety of functions within the cell such as reloading of synaptic vesicles with vesicular components at the active site through receptor-mediated endocytosis.

endorphins: endogenous opioid peptides, 31 amino acids in length, derived from proopiomelanocortin.

endothelins: 21-Amino-acid peptides produced by vascular endothelial cells and functioning as potent vasoconstrictors.

The endothelin family consists of three members, ENDOTHELIN-1; ENDOTHELIN-2; and ENDOTHELIN-3. All three peptides contain 21 amino acids, but vary in amino acid composition. The three peptides produce vasoconstrictor and pressor responses in various parts of the body. However, the quantitative profiles of the pharmacological activities are considerably different among the three isoforms.

enkephalins: short endogenous opioid peptides derived from proenkephalin and proopiomelanocortin.

epidemiology: science of the incidence, distribution, and control of disease in a population.

epidermal growth factor (EGF): a 6-kDa polypeptide growth factor initially discovered in mouse submaxillary glands. Human epidermal growth factor was originally isolated from urine based on its ability to inhibit gastric secretion and called urogastrone. EGF exerts a wide variety of biological effects including the promotion of proliferation and differentiation of mesenchymal and epithelial cells.

epinephrine: an analog of norepinephrine that is formed in the adrenal medulla and acts primarily as a hormone on either alpha or beta adrenergic receptors. Responsible for the “fight or flight” response to danger.

EPSC: excitatory postsynaptic currents are the flow of ions resulting in EPSP

EPSP: excitatory postsynaptic potentials are temporary increases in postsynaptic membrane potentials caused by the flow of positively charged ions into the postsynaptic cell. The influx of positively charged ions leads to an excitatory response therefore simplifying the neuron’s generation of an action potential.

Epstein Barr virus (EBV): a gamma human herpesvirus.

exocytosis: vesicles carrying molecules to be secreted from the cell merge with the cell membrane resulting in the vesicular contents being released to the exterior of the cell. This is the method by which neurotransmitters are released at the active site.

experimental allergic encephalomyelitis (EAE): an animal model of brain inflammation, used mostly with rodents, and serves as a model of the human disease multiple sclerosis.

experimental allergic neuritis (EAN): animal model of acute inflammatory demyelinating polyradiculoneuropathy that shares many features with human GBS. EAN can be induced in rodents, rabbits, and monkeys by immunization with peripheral nerve homogenate, myelin, and myelin proteins such as P0.

F

facilitated diffusion: A process of passive transport where molecules move across membranes with the assistance of transport proteins

family-based association study: is an association study that uses families as the source, where the parents are the controls and affected are their offspring.

Fas: Fas/APO-1/CD95 (36kDa) is a member of the tumor necrosis factor (TNF) receptor superfamily. Fas has been shown to be an important mediator of apoptotic cell death, as well as being involved in inflammation.

fatal insomnia: rare prion disease of humans that is initially characterized by sleeplessness, later developing into hallucinations, followed by extreme weight loss, dementia and finally death

ferritin: iron-containing proteins that are widely distributed in animals, plants, and microorganisms. Their major function is to store iron in a nontoxic bioavailable form. Each ferritin molecule consists of ferric iron in a hollow protein shell (apoferritins) made of 24 subunits of various sequences depending on the species and tissue types.

fibroblast growth factor (FGF)-2: a single-chain polypeptide growth factor that plays a significant role in the process of wound healing and is a potent inducer of physiologic angiogenesis. Several different forms of the human protein exist ranging from 18–24kDa in size due to the use of alternative start sites within the fgf-2 gene. It has a 55% amino acid residue identity to fibroblast growth factor 1 and has potent heparin-binding activity. The growth factor is an extremely potent inducer of DNA synthesis in a variety of cell types from mesoderm and neuroectoderm lineages. It was originally named basic fibroblast growth factor based upon its chemical properties and to distinguish it from acidic fibroblast growth factor (Fibroblast Growth Factor 1).

fetal liver kinase (Flk)-2: a member of the tyrosine kinase receptor family, this 135–150-kDa molecule is expressed by multipotential progenitor cells including primitive B cell and myelomonocytic progenitors in fetal liver and adult bone marrow. Also called as Fms-like tyrosine kinase 3 (Flt3) and CD135 in human.

follicular dendritic cells (FDCs): cells found in lymph follicles that present immune complexes to B cells, aiding in B cell maturation.

fovea: the high acuity region of the retina upon which the center of the visual image is focused. The fovea contains only cones.

G

gadolinium: a radio-opaque dye injected in conjunction with magnetic resonance imaging (MRI) to evaluate the brain parenchyma for breaches in the cerebrovascular system.

ganglia: a collection of cell bodies of the postganglionic motor neurons which join synapse with nerves from the central nervous system; they act as relay stations for CNS

impulses to peripheral effector cells and as control loops for reflex actions.

gangliosides: sialic acid-containing glycosphingolipids which are widely distributed in mammalian tissues but highly enriched in the nervous system, due to their incorporation into the myelin sheath. Gangliosides consist of a tetraose core to which variable numbers of sialic acids are attached; the ceramide or lipid portion of the molecule is attached to the internal glucose. GM1, GD1b, GD1a, and GT1b are the most abundant complex gangliosides in the nervous system.

gap junctions: gap junction or nexus is a junction between certain animal cell-types that allows cell-to-cell passage of ions, hormones, and neurotransmitters. One gap junction is composed of two connexons (or hemichannels), which connect across the intercellular space, therefore connecting the cytoplasm of the cells. They are analogous to the plasmodesmata that join plant cells.

GATA3: binding protein 3. GATA-3 expression inhibits the differentiation of Th1 cells *in vivo*, induces Th2 cell differentiation, and increases functional capacity to secrete Th2 cytokines and enhance surface expression of markers for antigen-experienced Th2-committed cells. GATA-3 expression must be sustained to maintain the Th2 phenotype.

GDNF: glial cell line-derived neurotrophic factor is the founding member of the glial cell line-derived neurotrophic factor family. It was originally characterized as a nerve growth factor promoting the survival of midbrain dopaminergic neurons, and it has been studied as a potential treatment for Parkinson disease.

general anesthetics: a group of diverse agents used in surgery to produce loss of pain perception and loss of consciousness. They depress most CNS modalities, including respiration.

gene arrays: high throughput technique used to analyze different expression profiles using a collection of gene-specific nucleic acids.

gene modifiers: are genes that affect the expression of the phenotype of a trait.

genetic heterogeneity: describes when a disorder has more than one genetic cause that causes the same clinical presentation.

genome: one haploid set of chromosomes with the genes they contain; *broadly:* the genetic material of an organism.

genomic convergence: a process in which multiple independent genomic research techniques are used to identify possible causal genes, with the overlap between the results in each technique converged to produce the genes with the highest likelihood of being involved in the disorder.

Genomics: field of science that combines genetics and molecular biology techniques to create genetic maps and DNA

sequences; analyze and organize genetic information into databases.

genotype association: association with a specific genotype but not necessarily an allele.

germinal center: a lymphoid structure that arises within follicles after immunization with, or exposure to, a T-cell-dependent antigen. It is specialized for facilitating the development of high-affinity, long-lived plasma cells and memory B cells.

Gerstmann-Straussler-Scheinker (GSS): syndrome is a prion disease linked to germ line mutations or insertions in the human prion protein gene resulting in a neurodegenerative brain disorder.

GFAP: glial fibrillary acidic proteins form the main intermediate filament in astrocytes and are therefore used as the marker protein of astrocytes.

glatiramer acetate: an FDA approved therapy for relapsing remitting multiple sclerosis that

consists of acetate salts of polypeptides that are found in myelin and contains four naturally

occurring amino acids randomly synthesized: L-glutamic acid, L-alanine, L-tyrosine, and L-lysine; available as Copaxone, 20mg of glatiramer acetate and 40mg of mannitol for subcutaneous injection daily.

glia: non-neural cellular element that has diverse functions in the nervous system including participation in innate immunity, myelin formation, signal transmission, and homeostasis maintenance.

glial activation: refers to activation of glial cells (astrocytes and microglia) in response to proinflammatory stimuli triggered by injury or disease. This can usually be detected by the presence of glial fibrillary acidic protein (GFAP) in astrocytes.

glial scar: scar formed due to insults to the CNS.

glucocorticoids: steroid hormones (esp. cortisol in humans) produced by the adrenal cortex in response to stressful stimuli.

glutamate: the most important excitatory neurotransmitter in the CNS. Glutamate binds to either metabotropic, or ionotropic receptors. Ligation of glutamate at the NMDA receptor—one of the ionotropic receptors—induces calcium influx into the neuron. Astrocytes are crucially involved in glutamate metabolism, storage and re-uptake.

glutamine: an amino acid that is formed from glutamate. Glutamine in excess is toxic for the brain.

growth factor: growth factors stimulate cell proliferation and/or differentiation during embryonic development, tissue growth and wound healing. The term “growth factors,” used in

this chapter, also refers to a broad range of structurally diverse molecular families and individual proteins.

guanine nucleotide binding proteins (G-proteins): membrane-associated, heterotrimeric proteins composed of three subunits: alpha, beta and gamma subunits. G proteins and their receptors (GPCRs) form one of the most prevalent signaling systems in mammalian cells, regulating systems as diverse as sensory perception, cell growth and hormonal regulation. Binding of ligands such as hormones and neurotransmitters to a G-protein coupled receptors causes a conformational change, which in turn activates the bound G protein on the intracellular-side of the membrane. The activated receptor promotes the exchange of bound GDP for GTP on the G protein alpha subunit.

Guillain Barré syndrome: an acute monophasic neuropathy characterized by an autoimmune response to peripheral myelin, and is the most common acquired demyelinating peripheral neuropathy. Pathogenesis involves mononuclear cell infiltration in the peripheral nerves, along with both B cells and CD4+ helper T cells. Symptoms begin as tingling sensations and weakness in the legs and in extreme cases can lead to the development of total paralysis. Current treatment include high-dose intravenous Ig and plasma exchange.

H

hallucinations: sensory misperceptions in which a person will experience an auditory, visual, or other sensory experience in the absence of an observable stimuli

haplogroup: a haplotype of the mitochondrial genome.

Haplotype: with two polymorphisms in linkage disequilibrium the alleles of those two polymorphisms travel together as a single combined allele or haplotype.

herpes simplex virus (HSV): A naturally neurotropic virus capable of establishing latent infection within neurons, but also possesses the ability to infect a wide range of cellular targets. Recombinant HSV vectors comprise a wild-type HSV genome rendered replication defective via disruption/deletion of an indispensable viral gene(s). Typically, the immediate-early gene loci, which encode for potent transactivation proteins that initiate the viral lytic cycle, are targeted for insertion of therapeutic transcription units via homologous recombination. The HSV-1 amplicon, another type of HSV vector, is a uniquely designed eukaryotic expression plasmid that harbors two non-protein encoding virus-derived elements: an HSV origin of DNA replication (OriS) and the cleavage/packaging sequence (“a” sequence). Both *cis* sequences are specifically recognized by HSV proteins to promote the replication and incorporation of the vector genome into viable viral particles, respectively. This highly versatile plasmid can be readily manipulated to contain desired promoters, enhancers, and transgenes of substantial size (~130kb).

hemorrhagic stroke: accounts for 15–20% of all strokes. Rupture of a blood vessel into the brain parenchyma results in an intracerebral hemorrhage (ICH); this is commonly caused by hypertension-induced vascular disease of the small perforating intracranial arteries. Rupture of a vessel into the subarachnoid space results in a subarachnoid hemorrhage; this most commonly results from rupture of a brain aneurysm or an arteriovenous malformation.

high endothelial venules (hevs): specialized venules found in lymphoid tissues, which are the site of entry for lymphocytes from the bloodstream into lymph nodes and Peyer's patches.

hippocampus: part of the brain located inside the temporal lobe. It forms a part of the limbic system and plays a part in memory and spatial navigation.

histone acetyl transferase: enzymes that acetylate conserved lysine residues on histone proteins by transferring an acetyl group from acetyl CoA to form -N-acetyl lysine.

histone deacetylase: a class of enzymes that remove acetyl groups from an -N-acetyl lysine on histones.

HIV-1 associated dementia: HIV-1 associated dementia is a cognitive disorder specific to HIV, HAD is the clinical consequence of HIV-1 infection in the CNS and chronic inflammatory response that ultimately causes neuronal damage.

horizontal cell: lateral inhibitory interneuron in the outer retina.

HTLV-I-associated myelopathy/tropical spastic paraparesis (HAM/TSP): a chronic progressive inflammatory disorder of the CNS caused by infection with HTLV. This disorder affects 0.25–3% of HTLV-I-infected individuals.

human herpes virus 6 (HHV-6): a beta human herpesvirus, which is a common opportunistic viral infection for the immunosuppressed.

hypothalamo-pituitary-adrenocortical (HPA) axis: the major endocrine route in stress response. Activation of the HPA axis results in the secretion of corticotropin-releasing factor (CRF) from the hypothalamic paraventricular nucleus (PVN), adrenocorticotropin (ACTH) from the pituitary, and glucocorticosteroids (cortisol) from the adrenal cortex. Cytokines such as IL-1, IL-6, TNF- α are known to activate the HPA axis.

human leukocyte antigen (HLA): the genetic designation for the human major histocompatibility complex (MHC). This group of genes resides on chromosome 6, and encodes cell-surface antigen-presenting proteins and many other genes. Individual loci are designated by upper-case letters, as in HAL-A, and alleles are designated by numbers, as in HLA-A0201. HLA-B27 is a genetic marker present in patients alkylating spondylitis and Reiter's syndrome

human T cell lymphotropic virus type I (HTLV-I): an exogenous human retrovirus that infects 10–20 million people

worldwide. Endemic areas of HTLV-I infection include southern Japan, certain regions of Africa and South American, and the Caribbean. HTLV-I is the etiologic agent of both an aggressive T cell leukemia and an inflammatory disorder of the CNS.

Huntingtin (htt): a causative gene of Huntington's Disease (HD), with its N-terminal CAG trinucleotide repeat expansion correlated with the onset of the disease. Predicted to function as a scaffolding molecule for multiple transporting/transcriptional molecules in cytoplasm and nucleus. Inclusion of htt and/or its N-terminal polyglutamine tract have been proposed as a potential mechanism of neurodegeneration in HD.

Huntington Disease: a progressive neurodegenerative disorder that is inherited as an autosomal dominant trait, that usually begins in middle age, that is characterized by choreiform movements (involuntary, rapid, jerky movements) and mental deterioration leading to dementia. Histologically, Huntington disease shows atrophy of the caudate nucleus and the loss of brain cells with a decrease in the level of several neurotransmitters—called also Huntington's—abbreviation HD:

hydrophilicity: a physico-chemical characteristic of a compound attributed to its ability to dissolve in water solutions.

hyphenated techniques: combination of individual techniques, such as liquid chromatography (LC) and mass spectrometry (MS), to create one encompassing method (LC-MS) capable of new analytical possibilities.

hypomania: a less severe and less persistent form of mania. Seen in such disorders as bipolar II and cyclothemia.

hypothalamic-pituitary-adrenal (HPA) axis: neuroendocrine pathway that mediates the stress response by regulating systemic cortisol levels and brain CRH levels.

I

ID2: a helix-loop-helix protein that can inhibit transcription factors with a basic helix-loop-helix motif. Besides its role in lymphoid organogenesis, ID2 is required for the generation of natural killer cells.

IFN β -1a: an FDA approved therapy for relapsing remitting multiple sclerosis. IFN β -a is available as Avonex (Biogen-Idec) 33 mcg for intramuscular injection (IM) once a week and Rbif (Serono) with doses of 22 mcg and 44 mcg for subcutaneous (SQ) injection 3 \times /week.

IFN β -1b: an FDA approved therapy for relapsing remitting multiple sclerosis, available as Betaseron for subcutaneous injection 22 μ g (6 MIU) per dose for 66 μ g/week and 44 μ g (12 MIU) per dose for 132 μ g/week.

IKAROS: this gene encodes a family of zinc-finger transcription factors that regulate transcription required for the development of all lymphoid lineages, as well as lymph nodes and Peyer's patches.

IL-7R: a receptor for interleukine 7 (IL-7). The function of this receptor requires the interleukin 2 receptor, gamma chain (IL2R γ), which is a common gamma chain shared by the receptors of various cytokines, including interleukines 2, 4, 7, 9, 15, 21. This protein has been shown to play a critical role in the V(D)J recombination during lymphocyte development. This protein is also found to control the accessibility of the TCR gamma locus by STAT5 and histone acetylation. Knockout studies in mice suggested that blocking apoptosis is an essential function of this protein during differentiation and activation of T lymphocytes. The functional defects in this protein may be associated with the pathogenesis of the severe combined immunodeficiency (SCID).

imipramine: an agent effective in the treatment of depression that acts to increase neuronal activity by lengthening the duration of action of norepinephrine and/or serotonin in the neuronal synapse.

immune deviation: modification of cells having or producing antibodies or lymphocytes capable of an immune response to an antigen after prior exposure to that antigen.

immune neuropathies: heterogeneous group of neuropathies with an assumed autoimmune pathogenesis. This includes acute forms such as Guillain-Barré Syndrome (GBS) and chronic conditions such as chronic inflammatory demyelinating polyneuropathy (CIDP) as well as polyradiculoneuropathies associated with monoclonal paraprotein.

immune neuropathy: disease of the peripheral nerves that is mediated by autoimmune processes, either cellular or humoral autoimmunity

immune privileged: organs or tissues where entry of effector lymphocytes is blocked by anatomic barriers and is not recognized by immune cells due to absence or low levels of expression of MHC class I and II antigens.

immunoglobulins: natural immunomodulatory compounds that provide passive immunization and are used in a variety of diseases.

immunomodulator: a type of adjuvant that directly activates cells of the immune system, usually via cytokine release

immunosuppression: a decrease in any functional assay of immune competence from its baseline level in normal animals.

immunotherapy: the treatment of a disease by vaccination or by administering antibodies.

infliximab: chimeric anti-TNF- α monoclonal antibody. It is used in the treatment of rheumatoid arthritis and other autoimmune diseases.

innate immune system: the dominant system of host defense in most organisms. Innate immune defenses are non-specific, and do not confer long-lasting immunity against a pathogen.

inflammation: a local response to cellular injury that is marked by capillary dilatation, leukocytic infiltration, and often loss of function. Inflammation serves as a mechanism initiating the elimination of noxious agents and of damaged tissue:

insulin degrading enzyme (IDE): responsible for the degradation of the β -chain of insulin, expressed abundantly in microglia and also other neuronal cells in brain.

insulin like growth factor: resembles insulin but is contained in part of a complex used to communicate with their physiologic environment, contributing to cell such processes as proliferation and inhibition of cell death. The complex consists of two cell-surface receptors, two ligands, and six high affinity binding proteins.

intercellular adhesion molecule 1 (ICAM-1): molecules that promote adhesion between cells.

interferon-gamma: the major interferon produced by mitogenically or antigenically stimulated lymphocytes. It is structurally different from type I interferon and its major activity is immunoregulation. It has been implicated in the expression of class II histocompatibility antigens in cells that do not normally produce them, leading to autoimmune disease.

interferons (IFNs): natural and recombinant compounds with important immunomodulatory activities, such as inflammation, antigen presentation, and antiviral activity. IFN type I binds to IFN- α receptor complex, and IFN type II binds to IFN- γ receptor complex.

interleukin: a group of cytokines (secreted signaling molecules) that mediate autocrine, paracrine and endocrine communication between cells of the immune system and other systems of the body. They enhance cell proliferation and differentiation, proteins DNA produced by the cells of the immune system of most vertebrates in response to challenges by foreign agents such as viruses, bacteria, parasites and tumor cells. They were first seen to be expressed by white blood cells (leukocytes, hence the -leukin) as a means of communication (inter-). The name is something of a relic though; it has since been found that interleukins are produced by a wide variety of bodily cells. The function of the immune system depends in a large part on interleukins. They are designated by IL and a number. IL-1 causes fever. IL-12 biases towards a Th1 response. IL-10 is anti-inflammatory. IL-8 is chemotactic. The interleukins are comprised of some of the cytokines and some of the chemokines.

interleukin-2-recombinant form of IL-2: an immunostimulant used to treat adults with metastatic renal carcinoma and melanoma.

intraocular pressure: a measurement of the fluid pressure inside the eye. This fluid, or aqueous humor, nourishes the cornea, iris, and lens, and it helps the eye maintain its globular shape. Normal eye pressure, as measured by an eye doctor,

usually ranges between 10 and 21 mm of mercury, with an average of 16.

ion channel: protein that mediates the transport of ions across membranes through the formation of a pore in the cell membrane, therefore allowing for the establishment of a voltage gradient across the cell membrane.

ipratropium: a derivative of atropine that blocks the action of acetylcholine on muscarinic cholinergic receptors.

IRF4 and IRF8: IFN regulatory factors (IRFs) are a family of transcription factors involved in the regulation of both innate and adaptive immunity. By gene knockout studies, IRF1, IRF4, and IRF8 have been found to be essential for the proper differentiation and functions of immune cells. Lymphocyte development requires IRF1 and IRF4, whereas IRF7 and IRF8 are needed for monocyte-to-macrophage differentiation, and together with IRF1, IRF8 orchestrates the development of Th1 immune responses by regulating the gene expression of IL-12, the major Th1 immune response-inducing cytokine. Recently, IRF4 and IRF8 have also been shown to participate in DC differentiation and functions. An interesting feature of IRF4 and IRF8 is their ability to function as transcriptional activators and repressors, depending on the promoter context.

ischemic stroke: account for around 80–85% of all strokes and are nearly always caused by arterial vascular occlusions; rarely occlusion in the cerebral venous system may result in ischemic and/or hemorrhagic stroke.

isoproterenol: an analog of norepinephrine that mimics norepinephrine action primarily at the beta adrenergic receptors. It is used to treat asthma, chronic bronchitis, and emphysema; by relaxing the airways to allow for increased airflow.

isotypes: classification of various immunoglobulins by the type of chain they are composed of. This classification varies between species.

J

JAK–STAT pathway: a signaling pathway utilized by cells to respond to cytokines and growth factor stimuli. This pathway transduces the signals carried by cytokines to the cell nucleus, where activated STAT proteins modify gene expression. JAKs—Janus Kinases; STATs—Signal Transducers and Activators of Transcription.

K

keratinocytes: epithelial cells dividing in the stratum basale of the epidermis, they accumulate keratin, undergo apoptosis and are sluffed off at the skin surface. In psoriasis, the cycle is accelerated from 30 days to 7–10 days.

KIRs: killer immunoglobulin like receptors are MHC-binding receptors on NK cells that triggers NK cell-mediated responses. KIRs diversify human natural killer cell populations

and T cell subpopulations. Ly49, the analogous system in rodents.

Kuru: a prion disease of the Fore speaking tribes in the New Guinea highlands in which disease was transmitted via endocannibalism.

kynurenic acid: the only known endogenous NMDA receptor antagonist. Kynurenic acid is the end product of a side arm of the kynurenine pathway. Besides its neuroprotective NMDA binding properties, kynurenic acid also blocks the $\alpha 7$ nicotinic acetylcholine receptor.

kynurenine pathway: more than 95% of tryptophan in the organism are metabolized through the kynurenine pathway, which is entitled by the first stable intermediate, kynurenine. The activity of one of the key enzymes, indoleamine 2,3-dioxygenase, is regulated by cytokines: IFN- γ and TNF- α are inducers, while IL-4 and IL-10 are inhibitors of IDO. Neuroactive kynurenine pathway intermediates include the free-radical generators 3-hydroxykynurenine, 3-hydroxyanthranilic acid, and quinolinic acid. The latter is also an excitotoxic NMDA receptor agonist. The major end product of the kynurenine pathway is nicotinamide adenine dinucleotide phosphate (NADP⁺/NADPH), a major source of electrons e.g. for reductive biosynthesis.

L

learned helplessness: a condition induced by inescapable, unavoidable, unpleasant stress, in which impaired coping and maladaptive behavior results.

LEF1: lymphoid enhancer-binding factor 1 is a 48-kDa nuclear protein expressed in pre-B and T cells. LEF1 binds to a functionally important site in the T-cell receptor- α enhancer and confers maximal enhancer activity. LEF1 belongs to a family of regulatory proteins that share homology with high mobility group protein-1.

lentivirus: a member of the retrovirus family of enveloped RNA viruses associated with causing serious immunosuppressive diseases (i.e., AIDS). Vectors derived from lentiviruses can harbor a transgene up to 9 kb in size and express the transgene *in vivo* months to years.

leucine-rich repeat kinase-2 (LRRK2): a complex protein with multiple domains, including a leucine-rich repeat (LRR), a ROC-COR GTPase, a mitogen-activated protein kinase kinase, and WD40 domains. Mutations have been found in all domains in LRRK2 and have been identified as the cause of the late-onset, autosomal-dominant Park8 type of Parkinson's disease.

Lewy body: Intracytoplasmic neuronal inclusions which are intensely eosinophilic under routine haematoxylineosin stain. Immunocytochemically, Lewy bodies share epitopes with phosphorylated and non-phosphorylated α -synuclein, neurofilament subunits, tubulin, microtubule-associated protein 1 and 2, and

positively immunostain with ubiquitin. Lewy bodies are classically associated with Parkinson's disease, but also are present in a distinct form of dementia termed diffuse Lewy body disease, described recently in the elderly.

limbic system: an interconnected system of brain nuclei associated with basic needs and emotion, for example hunger, pain, pleasure, satisfaction and instinctive motivation.

lin: lineage marker negative cells are those lacking distinctive antigen associated with lymphoid, myeloid, erythroid or natural killer cells.

linkage: describes the relationship between two measurable traits that travel together through a pedigree more than expected by chance, suggesting the two lie physically near each other.

linkage disequilibrium: two genetic variations that lie physically close to each other (linkage) and travel together through multiple generations in a population unchanged. This means the allele of one variation will be on the same piece of DNA as a specific allele of another variation, and thus they are correlated. This correlation can be measured and is referred to as linkage disequilibrium. The actual term comes from the fact that these variations do not follow the expectations of Hardy-Weinberg equilibrium and thus are in disequilibrium do to linkage.

lipophilicity: a physico-chemical characteristic of a nonpolar compound attributed to its ability to dissolve in organic solvents.

lipopolysaccharide (LPS): large molecule consisting of a lipid and a polysaccharide (carbohydrate) joined by a covalent bond. LPS is a major component of the outer membrane of Gram-negative bacteria, contributing greatly to the structural integrity of the bacteria, and protecting the membrane from certain kinds of chemical attack. LPS is an endotoxin, and induces a strong response from normal animal immune systems. LPS acts as the prototypical endotoxin, because it binds the CD14/TLR4/MD2 receptor complex, which promotes the secretion of proinflammatory cytokines in many cell types, particularly in macrophages.

liposome: a spherical vesicle with a membrane composed of a phospholipid and cholesterol bilayer.

long terminal repeat: a region of the retroviral genome principally involved in mediating insertion of the viral genome into the host chromosome.

long-term potentiation: a long-lasting enhancement of synaptic efficacy. Regarded as a primary mechanism in memory formation.

Ly49: killer cell lectin-like receptor subfamily A, member 1. Analogous for human KIRs. A natural killer cell receptor.

lymphoid chemokines (CCL-13, -21): these chemotactic cytokines are constitutively expressed in lymphoid tissues and mediate the formation and maintenance of micro-domains in lymphoid organs. (See chemokines)

lymphotoxin (lt): protein belongs to the tumor-necrosis factor family and can be produced as a secreted homotrimer, LT β , or as a membrane-bound heterotrimer, LT $\alpha_1\beta_2$. The heterotrimer LT $\alpha_1\beta_2$ binds to the lymphotoxin-receptor (LTR). LT β is an inducer of the inflammatory response system and involved in normal development of lymphoid tissue.

M

macrophage: a phagocytic cell of the reticuloendothelial system or mononuclear phagocyte system that may be fixed or freely motile. Myeloid-derived cell of the innate immune system matures from a monocyte, and functions in the protection of the body against infection and noxious substances.

magnetic resonance imaging (MRI): the use of a nuclear magnetic resonance spectrometer to non-invasively produce electronic images of specific atoms and molecular structures in solids, especially human cells, tissues, and organs.

magnocellular ganglion cells: large retinal ganglion cells with low resolution but high sensitivity to intensity changes and motion.

major depressive disorder: a mental illness characterized by a persistent low mood and decreased interest and pleasure, as well as symptoms such as loss of energy and sleep and appetite disturbances

major histocompatibility complex (MHC): a large genomic region with the primary immunological function to bind and "present" antigenic peptides on the surfaces of cells for recognition (binding) by the antigen-specific T cell receptors (TCRs) of lymphocytes. Differential structural properties of MHC class I and class II molecules account for their respective roles in activating different populations of T lymphocytes. Class I molecules play a central role in the immune system by presenting peptides derived from the endoplasmic reticulum lumen. They are expressed in nearly all cells. The class II molecule plays a central role in the immune system by presenting peptides derived from extracellular proteins. Class II molecules are expressed in antigen presenting cells (APC: B lymphocytes, dendritic cells, macrophages).

mania: a phase of bipolar disorder characterized by elevated or irritable mood, as well as symptoms such as increased high risk behavior and decreased need for sleep.

mantle zone: the area of a secondary follicle that surrounds the germinal center and contains IgD⁺ naive, resting B cells.

mass spectrometry: technique used to measure the mass-to-charge ratio of ions to identify the components of a sample.

MAP kinase pathways: signaling pathway utilized by cells to respond to extracellular stimuli. Activation of this pathway regulates varied cellular activities including gene expression, mitosis, differentiation, and cell survival/apoptosis.

MDR inhibitor: a compound terminating multidrug resistance in cells.

mecamylamine: a synthetic compound which blocks the effect of acetylcholine at autonomic ganglia.

medium spiny neurons (MSNs): the most numerous and principal projection neurons from the striatum. The death of GABAergic MSNs in the striatum is associated with Huntington's Disease.

melanocortin-1 receptors: G-protein-coupled receptors that are stimulated by α -MSH (melanocyte stimulation hormone). These receptors are found in pigmented cells as well as immune cells.

melanopsin: the photopigment found in intrinsically light-sensitive ganglion cells involved in setting circadian rhythms.

mendelian disease: a disease caused by a single gene mutation such as sickle-cell anemia.

meningitis: inflammation of the meninges and especially of the pia mater and the arachnoid.

metallothionein(MT)-I/II: a family of Cys-rich, low molecular weight (MW ranging from 3500 to 14000Da) proteins. MTs have the capacity to bind both physiological (such as Zn, Cu, Se) and xenobiotic (such as Cd, Hg, Ag) heavy metals through the thiol group of its cysteine residues, which represents nearly the 30% of its amino acidic residues. Important to uptake, transport and retention of metals.

mGluR6: type III metabotropic glutamate receptor that mediates responses of ON type bipolar cells in the vertebrate retina. mGluR6 couples to the G protein, G_o , stimulating a signaling cascade that causes the closing of cation channels.

micelle: an aggregate of surfactant molecules dispersed in a liquid colloid. A typical micelle in aqueous solution forms an aggregate with the hydrophilic "head" regions in contact with surrounding solvent, sequestering the hydrophobic tail regions in the micelle center.

microglia: cells derived from myeloid progenitor cells (as are macrophages and dendritic cells) which come from the bone marrow and are key cellular mediators of neuroinflammatory processes in the CNS.

mitogen: A substance that induces cell division in lymphocytes in an antigen nonspecific way. Concanavalin A (Con A) is extracted from the Jack Bean plant and triggers T cell proliferation. Lipopolysaccharide (LPS) is part of the outer membrane of Gram-negative bacteria and triggers B cell proliferation.

mitoxantrone: FDA approval for use in progressive MS; available as (Novantrone) with recommended dosage of 5–12 mg/mL IV every 3 months. Because of cumulative cardiotoxicity, the drug can be used for only 2–3 years for a cumulative dose of 120–140 mg/m².

molecular adjuvant: an adjuvant comprised of a single molecular entity that targets antigens to and/or activates specific pathways of antigen processing and presentation.

molecular mimicry: immunological mechanism, whereby epitopes incidentally shared by microbial antigens and target tissues elicit an autoreactive T- or B-cell response in the wake of an infective illness. This autoimmune response then injures the "self" target tissues.

monoclonal antibody: a laboratory-produced antibody clone of one isotype that reacts to a single epitope.

mononuclear phagocytes (MP): phagocytic cells that typically initiate the host immune response. Mononuclear phagocytes include monocytes, mature macrophage, microglia and dendritic cells. These cells are widely distributed throughout the body in blood, tissue, and immune tissue identifying pathogens and steering the immune response, as well as clearing debris.

mood disorders: mental disorders characterized by inappropriate or abnormal emotional states, such as depression and bipolar disorder.

mood stabilizers: pharmacological agents used to treat bipolar disorder, including lithium, valproate, carbamazepine, and lamotrigine.

morphine: an alkaloid present in opium, an extract of the poppy plant, which binds principally to the mu opioid receptor and relieves pain.

MPP⁺: a product of MPTP metabolism, capable of inducing a Parkinson like state through inhibition of complex I of the electron transport chain. (see MPTP)

MPTP: 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine, a lipophilic pro-neurotoxin that is metabolized by monoamine oxidase B to the active dopaminergic toxin, 1-methyl-4-phenylpyridinium (MPP⁺).

muromonab-CD3: a monoclonal antibody directed at the epsilon chain of CD3 adjacent to the T cell receptor on human T lymphocytes, preventing T-cell activation. It is indicated for the treatment of acute organ transplant rejection.

muscarine: an alkaloid which blocks the effects of acetylcholine at G protein-coupled cholinergic receptors in the peripheral (parasympathetic) and central nervous systems.

Muller cell: A radial glial cell that is the predominant glial cell type in retina.

multidrug resistance: the ability of pathologic cells to withstand chemicals that are designed to aid in the eradication of such cells.

Multiple Sclerosis: (abbreviated MS, also known as disseminated sclerosis or encephalomyelitis disseminata) a chronic, inflammatory, demyelinating disease that affects the central nervous system (CNS). MS can cause a variety of symptoms, including changes in sensation, visual problems, muscle weakness, depression, difficulties with coordination and speech, severe fatigue, cognitive impairment, problems with balance, overheating, and pain.

mutation: is a genetic change so severe that the disruption in the processing or gene function causes a disease by itself.

mycophenolate mofetil: a prodrug that is hydrolyzed to the active agent mycophenolate. Mycophenolate inhibits *de novo* purine synthesis and is indicated for prophylaxis of transplant rejection.

myelin: ensheathes the axons of the nervous system

myelin associated glycoprotein (MAG): a myelin protein that is a candidate autoantigen in multiple sclerosis.

myelin basic protein (MBP): an abundant component of myelin that is a candidate autoantigen in MS.

myelin inhibitors: adult mammalian central nervous system (CNS) lack the ability to regenerate after injury. This is due in part to inhibitors within myelin. These inhibitors are myelin-Nogo, myelin-associated glycoprotein (Mag) and oligodendrocyte myelin glycoprotein (Omgp).

MOG: myelin oligodendrocyte glycoprotein is a glycoprotein believed to be important in the process of myelination of nerves in the central nervous system. The gene for MOG, found on chromosome 6, was first sequenced in 1995. It is a transmembrane protein expressed on the surface of oligodendrocyte cell and on the outermost surface of myelin sheaths. Interest in MOG has centered on its role in demyelinating diseases, particularly MS. Several studies have shown a role for antibodies against MOG in the pathogenesis of MS.

myelin sheath: the fatty substance that surrounds and protects some nerve fibers.

myelination: the formation of the myelin sheath around a nerve fiber.

N

NADPH oxidase: nicotinamide adenine dinucleotide phosphate oxidase, a primary producer of reactive oxygen species.

nanofiber: a microscopic fiber whose diameter is measured in nanometers.

nanogel: a nanoscale size polymer network of cross-linked chains.

nanoparticle: a microscopic particle whose size is measured in nanometers.

nanosphere: a microscopic hollow particle whose size is measured in nanometers.

nanosuspension: a colloidal dispersion (mixture) in which a finely-divided species of a nanoscale size does not rapidly settle out.

nanotube: a microscopic tube whose diameter is measured in nanometers.

natalizumab: Tysabri is a recombinant humanized monoclonal antibody that binds to the $\alpha 4$ subunits of $\alpha 4\beta 1$ and $\alpha 4\beta 7$ integrins that are expressed on the surface of all leukocytes except neutrophils and inhibit the <4 mediated adhesion to their receptors. Effective in phase I/II FDA trials for MS it was withdrawn due to deaths from progressive multifocal Leukoencephalopathy

natural killer cell: a lymphocyte (white blood cell) that can kill target cells that express nonself proteins, such as viral antigens or tumor antigens.

neostigmine: an inhibitor of acetylcholinesterase which prolongs the actions of acetylcholine.

neprilysin: a neutral zinc metallopeptidases and important $A\beta$ degrading enzyme, which is involved in the clearance of $A\beta$ in the brain.

nerve conduction: salutatory propagation of nerve impulses along the axon

nestin: a large (200 kDa) intermediate filament protein found in developing rat brain. Often used as a specific marker of neuronal progenitor cells.

neural progenitor cells (NPC): the term progenitor cell is used to refer to immature or undifferentiated cells, typically found in post-natal animals. While progenitor cells share many common features with stem cells, the term is far less restrictive.

neuritis: inflammation of the peripheral nerve

neurodegeneration: a progressive loss of brain tissue structure or function due to a disease process; in the case of Alzheimer's and Parkinson's disease, due to accumulation of aggregated cellular products.

neurodegenerative diseases: the subset of neurological disorders that include neuron pathologies, but exclude diseases of the nervous system due to cancer, edema, hemorrhage, trauma, poisoning, hypoxia, etc.

neurofibrillary tangle (NFT): intraneuronal protein aggregates and a pathological hallmark of AD, composed of

filamentous hyperphosphorylated tau (PHF-tau) and other ubiquitinated proteins.

neurogenesis: the formation of nervous tissue through a process that involves proliferation, migration, differentiation, and survival of neural stem cells.

neuroimmune process: the biochemical and electrophysiological interactions between the NERVOUS SYSTEM and IMMUNE SYSTEM that result in regulation of the immune system by the nervous system.

Neuroinflammation: chronic, CNS-specific, inflammation that is mediated predominantly by microglia that may engender neurodegenerative events.

Neuroinvasion: the process by which prions enter the nervous system.

neuromelanin: A modified form of melanin pigment normally found in certain neurons of the nervous system, especially in the substantia nigra and locus ceruleus.

neuromyelitis optica: also known as Devic's disease, is a severe variation of a demyelinating disease affecting the optic nerve and spinal cord.

neuron: nerve cell that transmits nerve signals to and from the brain, consisting of a cell body, axon(s) and dendrite(s).

neuronal apoptosis: death of neurons via programmed cell death.

neuronal plasticity: refers to the changes that occur in the organization and/or function of the brain as a result of experience.

neuropeptides: endogenous compounds made of amino acids that act upon receptors within the nervous system.

neuroprotection: mechanisms that protect the brain from apoptosis (programmed cell death) or degeneration, following a brain injury or in the course of a neurodegenerative disorder.

neuroproteomics: analysis of proteins and protein complexes of the nervous system (see Proteomics).

neuropsychology: the science of integrating psychological observations on behavior and the mind with neurological observations of the brain and nervous system.

neuroregeneration: the regrowth or repair of the nervous system or its components: tissues, cells or cell products.

neurosphere: a spherical group of neural progenitor cells growing in a suspension culture.

neurotoxin: a toxic complex typically of protein that acts preferentially on the nervous system.

neurotransmitter: chemical that mediates information transfer between neurons.

neurotrophin: a small secretory molecule needed for growth, maintenance, or repair in the nervous system

neurovascular unit: a composition of endothelial cells, astrocytes, neurons, and a contractile apparatus of either smooth muscle cells or pericytes that form a functionally integrated network.

NF- κ B: transcription factor found in all cell types and is involved in cellular responses to stimuli such as stress, cytokines, free radicals, ultraviolet irradiation, and bacterial or viral antigens.

NG2: expressed by a variety of immature glia in the CNS including oligodendrocyte progenitor cells, paranodal astrocytes and perisynaptic glia. The protein has a large extracellular domain with two LNS/Lam G domains at the N-terminus and a short intracellular tail with a PDZ-recognition domain at the C-terminus.

nicotine: an alkaloid that blocks the effects of acetylcholine at ligand-gated ion channels in the peripheral (parasympathetic and somatic) and central nervous systems.

nigrostriatal pathway: the neural pathway connecting the substantia nigra to the striatum.

nitric oxide: a free radical gas produced endogenously by a variety of mammalian cells, synthesized from arginine by nitric oxide synthase. Nitric oxide is one of the endothelium-dependent relaxing factors released by the vascular endothelium and mediates vasodilation. It also inhibits platelet aggregation, induces disaggregation of aggregated platelets, and inhibits platelet adhesion to the vascular endothelium. Nitric oxide activates cytosolic guanylate cyclase and thus elevates intracellular levels of cyclic gmp.

nitric oxide signaling: nitric oxide is a gaseous molecule released from the vascular endothelium in response to a variety of chemical and physical stimuli. It triggers smooth muscle cells in the vessel wall to relax by activating soluble guanylate cyclases (sGC), increasing the cyclic guanosine monophosphate (cGMP) concentration and activating the protein kinase G.

NMDA hypothesis: based on the observation that NMDA receptor antagonists like phencyclidine frequently induce schizophrenia-like psychotic symptoms, the NMDA hypothesis of schizophrenia proposed an endogenous NMDA receptor antagonist that may be expressed in higher amounts in individuals suffering from schizophrenia. Because of the close functional relationship between glutamatergic neurotransmission via NMDA receptors and dopaminergic neurotransmission, the NMDA hypothesis includes the generally accepted disturbance of dopamine signaling in schizophrenia.

NMDA receptor: n-methyl-d-aspartate receptor, named for the chemical agonist NMDA. The receptor is a heterodimer, forming an ionic channel that opens upon the binding of agonists

glutamate and glycine. NMDA receptors are permeable to a number of ions, but primarily sodium and calcium. NMDA function is fundamental to proper CNS function, but overstimulation is harmful resulting in excitotoxicity.

nociception: pain perception.

nociception/orphanin FQ: an endogenous opioid peptide that acts on the nociceptin/Orphanin FQ receptor.

node of ranvier: one of the many gaps in the myelin sheath—this is where the action potential occurs during saltatory conduction along the axon.

norepinephrine: the chemical responsible for transmitting impulses between neurons in the central and peripheral (sympathetic) nervous systems and acts on either alpha or beta adrenergic receptors.

notch: family of evolutionarily conserved proteins that regulates a broad spectrum of cell-fate decisions and differentiation processes during fetal and post-natal development. The best characterized role of Notch signaling during mammalian hematopoiesis and lymphopoiesis is the essential function of the Notch1 receptor in T-cell lineage commitment. More recent studies have addressed the roles of other Notch receptors and ligands, as well as their downstream targets, revealing additional novel functions of Notch signaling in intra-thymic T-cell development, B-cell development and peripheral T-cell function.

nuclear hormone receptor: receptor in which hormone binding is required to control the activity of the nuclear receptor.

nucleus: the organelle in the cell body of the neuron that contains the genetic material of the cell.

O

ocular immunology: a branch of immunology studying immune processes in the eye

ocular inflammation: an inflammatory process affecting the eye:

olfactory bulb: ovoid body resting on the cribriform plate of the ethmoid bone where the olfactory nerve terminates. The olfactory bulb contains several types of nerve cells including the mitral cells, on whose dendrites the olfactory nerve synapses, forming the olfactory glomeruli. The accessory olfactory bulb, which receives the projection from the vomeronasal organ via the vomeronasal nerve, is also included here.

oligoclonal bands (OCB): bands of immunoglobulins that are seen when a patient's blood plasma or cerebrospinal fluid (CSF) is analyzed by protein electrophoresis:

oligodendrocytes: are myelin-synthesizing cells of the CNS.

opiate peptides: endogenous peptides with opiate-like activity. The three major classes currently recognized are the ENKEPHALINS, the DYNORPHINS, and the

ENDORPHINS. Each of these families derives from different precursors, proenkephalin, prodynorphin, and PRO-OPIOMELANOCORTIN, respectively. There are also at least three classes of OPIOID RECEPTORS, but the peptide families do not map to the receptors in a simple way.

opioids: substances typically used to relieve pain through the binding of opioid receptors.

opioid receptors: G-protein-coupled receptors that are the targets of the endogenous opioid peptides and of the opioid drugs, such as morphine.

opiopeptins: a general name for the whole class of endogenous peptides acting upon opioid receptors.

opsin: G-protein coupled receptor activated by light in photoreceptor outer segments. Cones have cone opsins and rods possess rhodopsin.

ORL-1 receptor: also known as the nociceptin/orphanin FQ receptor—a G-protein-coupled receptor for which the endogenous ligand is nociceptin.

oxidative damage: the oxidation of proteins, lipids, and DNA, which results in neuronal dysfunction. An important component of neuronal damage and aging, where neuroinflammation is significantly involved.

oxidative stress: an imbalance between formation and neutralization of reactive oxygen species.

outer segment: photoreceptor cell structure that contains visual pigments and the enzymatic machinery for phototransduction.

P

p53: protein 53 (TP53) is a transcription factor critical factor to the prevention of mutation that regulates the cell cycle and hence functions as a tumor suppressor.

p75^{NTR} signaling: a member of the tumor necrosis factor receptor superfamily that facilitates apoptosis during development and after injury to the CNS. It activates Jun kinase (JNK), caspases 9, 6, and 3 and accumulates cytochrome c within the cytosol.

paraquat: trade name for the herbicide N,N'-dimethyl-4,4'-bipyridinium dichloride. Dangerously poisonous to humans as the compound is easily reduced resulting in superoxide generation.

parasympathetic: the division of the autonomic nervous system that regulates various body functions and is active primarily during periods of rest.

Parkin: an E3 ligase in the ubiquitin-proteasome system. Parkin mutations have been associated with familial Parkinson's disease.

Parkinson's Disease (PD): a chronic progressive neurodegenerative disease chiefly of later life that is linked to decreased dopamine production due to loss of dopaminergic neurons in

the substantia nigra. The clinical features are tremor of resting muscles, rigidity, slowness of movement, impaired balance, and a shuffling gait—called also paralysis agitans. Current therapies include L-DOPA and deep brain stimulation.

Pax-5: paired box gene 5 (B-cell lineage specific activator). The PAX proteins are important regulators in early development, and alterations in the expression of their genes are thought to contribute to neoplastic transformation. The PAX5 gene encodes the B-cell lineage specific activator protein (BSAP) that is expressed at early, but not late stages of B-cell differentiation. Its expression has also been detected in developing CNS and testis. Therefore, PAX5 gene product may not only play an important role in B-cell differentiation, but also in neural development and spermatogenesis.

parvocellular ganglion cells: small retinal ganglion cells that possess the high resolution and color sensitivity required for fine feature analysis and color vision.

passive immunization: administering antibodies for temporary immune protection against an antigen. Immunity exists as long as the antibodies remain in the body.

PASAT: paced auditory sequential addition test is a segment of the multiple sclerosis functional composite that tests one component of cognitive function.

pathogen-associated molecular patterns (PAMPs): small molecular motifs consistently found on pathogens; recognized by toll-like receptors and other pattern recognition receptors (PRRs) in plants and animals.

peripheral benzodiazepine receptor: a G-protein-coupled receptor for benzodiazepines found primarily in the periphery, particularly in the immune system, such as microglia in brain.

peripheral blood mononuclear cells (PBMC): lymphocytes and monocytes isolated from the peripheral blood, usually by Ficoll Hypaque density centrifugation.

peripheral nervous system: part of the nervous system consisting of the nerves and neurons outside the central nervous system.

phenylephrine: a norepinephrine analog that mimics norepinephrine action primarily at the alpha adrenergic receptors.

photoreceptor: principle photo-sensitive cell in the retina

physostigmine: an inhibitor of acetylcholinesterase which acts to prolong the actions of acetylcholine.

PI-3 kinase Phosphoinositide 3-kinases: a family of enzymes that are capable of phosphorylating the 3 position hydroxyl group of the inositol ring of phosphatidylinositol.

PK11195: 1-(2-chlorophenyl-N-methylpropyl)-3-isoquinoline-carboxamide, a ligand for peripheral benzodiazepine receptors.

PLP: refers to proteolipid protein that is present in myelin.

polymorphism: a genetic variation in a base pair, repeat, deletion or duplication that is neutral or acts as a susceptibility allele

postsynaptic density: an electrondense region located opposite the active zone on the postsynaptic plasma membrane.

pralidoxime: a reactivator of acetylcholinesterase that has been inhibited by organophosphorus compounds.

prazosin: synthetic compound that blocks the action of norepinephrine on alpha adrenergic receptors.

preproenkephalin: a precursor peptide for the enkephalins. It is processed into proenkephalin before being converted to multiple enkephalin molecules.

presenilin-1 (PS1): a principal component of γ -secretase complex, processes APP at the γ -site, and a causative gene of the early onset of FAD. The γ -secretase complex is also critically involved in Notch processing and its signaling.

prion: infectious protein agent that induces a fatal neurodegenerative disease in animals and humans that is characterized by the accumulation of the abnormal isoform of the prion protein.

progenitor/precursor cell: a cell that can differentiate into multiple cell types and has limited self-renewal capacities, so that the cell can proliferate while maintaining its differential capability for a short period of time but not for the entire life of the organism.

proinflammatory cytokines: cytokines that induce an inflammatory response such as IFN- γ , IL-1(β), IL-18, and TNF- α . some authors also include IL-6, though this cytokine has an extremely broad range of actions.

proliferation: the ability to multiply cell population numbers by undergoing self-renewal or division.

proopiomelanocortin: a large precursor peptide that is the source of many active peptides, including some endorphins, enkephalins, alpha-MSH and others.

propranolol: a synthetic compound that blocks the action of norepinephrine on beta adrenergic receptors.

protein fingerprinting: method of classifying new protein families based on conserved regions within alignments of related proteins.

protein microarrays: high throughput technology to detect differentially expressed proteins using protein-protein interactions.

protein-only hypothesis: proposed by Dr. Stanley Prusiner to describe the novel properties of prions; prions are proteinaceous infectious particles that lack an agent-specific nucleic acid genome.

protein profiling: identification of proteins in a sample.

proteolipid protein (PLP): the most abundant myelin protein; a candidate autoantigen in MS:

proteomics: field of science using high throughput profiling techniques to analyze proteins expressed under a certain set of conditions within an individual cell or organism.

PU.1: spleen focus forming virus (SFFV) proviral integration oncogene *spi1*. The PU.1 plays indispensable and distinct roles in hematopoietic development through supporting HSC self-renewal as well as commitment and maturation of myeloid and lymphoid lineages.

R

radial glia: neuronal progenitor cells that arise from neuroepithelial cells after the onset of neurogenesis with more restricted differentiation abilities. In the developing nervous system, radial glia function both as neuronal progenitors and as a scaffold upon which newborn neurons migrate. In the mature brain, the cerebellum and retina retain characteristic radial glial cells. In the cerebellum, these are Bergmann glia, which regulate synaptic plasticity. In the retina, the radial Müller cell is the principal glial cell, and participates in a bidirectional communication with neurons.

randomized controlled trials: an experiment in which investigators randomly allocate eligible people into (e.g. treatment and control) groups to receive or not to receive one or more interventions that are being compared. The results are assessed by comparing outcomes in the treatment and control groups. This form of trial is often used in performing scientific research due to its reliability in avoiding false causality.

reactive oxygen species (ROS): generally very small molecules that are highly reactive due to the presence of unpaired valence shell electrons. They include oxygen ions, free radicals and peroxides both inorganic and organic. ROS are formed as a natural byproduct of the normal metabolism of oxygen and have important beneficial roles in cell signaling and innate immunity. However, during times of environmental stress ROS levels can increase dramatically, potentially resulting in significant damage to cell structures. This culminates into what is known as oxidative stress and can lead to such results apoptosis or necrosis.

redox signaling pathways: signal transduction pathways based on electron-transfer processes that play important messaging roles in biological systems. These pathways are activated by free radicals, reactive oxygen species (ROS), and other electronically-activated species and are turned off by reducing species.

regulatory T cells: also called suppressor T cells, regulatory T cells are a small population of CD4⁺ T cells that have regu-

latory (that is, suppressor) activities towards other cells of the immune system and serve to limit immune responses, particularly those which may be against host tissue. These cells express the transcription factor forkhead box P3 (FOXP3) which is used as a specific marker for these cells. An absence of T_{Reg} cells or their dysfunction is associated with severe autoimmunity.

relative risk: a statistical tool used to measure the ratio of two conditional probabilities. For example, in genetic disease inheritance, relative risk can measure the degree of genetic contribution to a trait, defined as the risk of the disease in first degree offspring (sibs, parents, offspring) of an affected individual relative to the risk of the disease in the general population.

reserpine: an alkaloid that prevents the accumulation of catecholamines such as norepinephrine and dopamine in the synapses. Reserpine performs this action by irreversibly binding to these neurotransmitters and inhibiting their uptake into synaptic vesicles. The compound has been used as an antihypertensive as well as a sedative but is rarely used any longer due to its risk of depression and the availability of better drug therapies.

resting membrane potential: membrane potential prevailing in a resting unstimulated cell. The value is often negative, indicating an excess of negative potential inside the cell in comparison with the external environment. The difference in potential is based on the ion concentrations within and surrounding the cell membrane, as well as the ion transport proteins embedded in the cell membrane.

retina: a thin sheet of neural cells at the back of the eye that is continuous with the optic nerve. The retina is responsible for phototransduction and the initial stages of vision. The retina's photoreceptor cells, called rods and cones, produce neural signals in response to light that then undergo complex processing by ganglion cells of the retina. The resulting information is sent to the brain via the optic nerve to be interpreted into a visual image.

retinal ganglion cell: the output cell of the retina whose axons form the optic nerve and project to higher visual center. These cells process the signals produced by the photoreceptor cells of the retina and then send the resulting information to the brain via the optic nerve for interpretation.

retinal pigment epithelium: the pigmented epithelial cells forming the outermost layer of the retina. This layer of cells is attached to the choroid vascular tissue and provides nourishment to the cells of the retina.

retinoid-related orphan receptor (ROR): an orphan nuclear hormone receptor that regulates the survival of CD4⁺CD8⁺ doublepositive (DP) thymocytes and is essential for the development of the lymph nodes and Peyer's patches.

retrovirus: any of a family (Retroviridae) of enveloped RNA viruses (such as HIV and numerous tumorigenic viruses) that

replicate in a host using a DNA intermediate produced using their RNA template and reverse transcriptase. Through the process, their viral genome is incorporated into the genome of infected cells. There are three common genes found in most retroviruses, the gag, pol, and env genes, which encode for the viral proteins, enzymes, and envelope of the viruses respectively.

ribbon: structure in synaptic terminals of photoreceptors, retinal bipolar cells, and hair cells that is specialized for sustained neurotransmitter release.

rivastigmine: an inhibitor of acetylcholinesterase which prolongs the actions of acetylcholine with prominent effects in the central nervous system. The compound has been shown effective in treating the symptoms of dementia associated with Alzheimer's disease.

RNA interference: a posttranscriptional genetic mechanism, which suppresses gene expression. In this mechanism, double-stranded RNA cleaved into small fragments initiates the degradation of a complementary messenger RNA. This pathway is thought to have developed as part of the innate immune system to protect against viruses, as in controlling development and genome preservation. This mechanism is used as a technique (as the introduction of double-stranded RNA into an organism) that artificially induces mRNA inhibition and is used for studying or regulating gene expression.

rod: a type of Photo-sensitive retinal cell mediating scotopic vision near visual threshold. These cylindrical-shaped photoreceptor cells are located primarily on the outer edges of the retina and are therefore used also for most peripheral vision.

rostral migratory stream: the route for neuronal precursors (periglomerular and granule cells) to migrate to the olfactory bulb where they differentiate into interneurons throughout the life of rodents. Overlying the rostral migratory stream is the anterior or olfactory limb of the anterior commissure (or commissura anterior pars bulbaris), which carries centrifugal fibers, including some from the medial forebrain bundle, to the region.

rotenone: a botanical insecticide that is an inhibitor of mitochondrial electron transport. Inhibition is achieved through the hindrance of the electron transfer chain preventing NADH from converting to ATP thus limiting usable cellular energy. The compound is considered moderately hazardous and mildly toxic to mammals, including humans.

S

Sca-1: a mouse member of the interferon-inducible Ly-6 family of genes that can conveniently be used as a marker for stem/early progenitor cells. Sca-1 is used to isolate many stem cells in the mouse. The density of this antigen declines with differentiation. Sca-1 belongs to a family of proteins bearing

a UPAR (urokinase plasminogen activator receptor) domain. The UPAR protein plays a role in cellular adhesion and migration by modulating integrin function and degradation of the extracellular matrix.

schizophrenia: a mental illness characterized by cognitive dysfunction, hallucinations, delusions, thought disorder and poor social and vocational functioning. The term can also be used to describe a group of mental disorders characterized by the same or similar indicators.

Schwann's cells: cells that produce myelin in the peripheral nervous system. These cells are located between the axon and axon terminal of neurons and create the myelin sheath which aides in insulating axons and in increasing impulse speeds as they are propagated through the neuron (allowing for salutatory conduction).

sclerosis: a hardening of tissue as a result of scarring or plaques such as in the central nervous system when formed by inflammatory perivascular lesions.

senility: a term once used to describe dementia.

sickness behavior: one of the immunological models of major depression. The cytokines IL-1, IL-6, and TNF- α have been identified to induce depression-like mood disturbance upon administration or during disease states that are accompanied by increased or over-production of these cytokines.

self-renewal: the ability of a cell to divide into two daughter cells with identical properties and retaining equal differential capabilities as the parent cell.

SCID: severe combined immunodeficiency, a genetic disorder in which both "arms" (B cells and T cells) of the adaptive immune system are crippled. This disease is fatal if untreated due to extreme susceptibility to infectious diseases.

single-chain antibodies: engineered antibodies composed of the minimal antibody-binding site formed by non-covalent association of the V_H and V_L variable domains joined by a flexible polypeptide linker. Sequences encoding eukaryotic secretion signals can be appended to the scFv genes and subsequently be cloned into gene transfer vectors for prolonged *in vivo* expression. These antibodies are significantly smaller than natural antibodies but retain the same affinity as natural antibodies and can be produced in large quantities at relatively low costs using biotechnology.

signal serotonin: serotonin (5-hydroxytryptamine, 5-HT) is a biogenic indoleamine derived from the dietary amino acid tryptophan. Serotonergic neurons are located almost exclusively in the raphe nuclei of the brainstem, but their projections innervate virtually all other parts of the central nervous system. A reduced serotonergic neurotransmission is supposed to play a crucial role in the pathophysiology of major depression among other disorders.

signal transduction: mechanism by which external stimuli are interpreted by cells. This transformation is often done through biochemical reactions involving secondary and cascade pathways within and between cells.

simian virus 5 (SV-5): a paramyxovirus belonging to the family Paramyxoviridae. The genomes of these viruses are composed of negative-sense single-stranded RNA and this family of viruses is responsible for a number of human and animal diseases.

single nucleotide polymorphism: the most common polymorphism in the human genome, a nucleotide polymorphism at a single base. The result of these differences creates alleles.

sirolimus: a macrolide antibiotic that inhibits T lymphocyte activation and proliferation. It is an immunosuppressive agent that is used mainly to prevent rejection during organ transplantation. The compound works to inhibit a response to interleukin-2 which is necessary to activate T cells.

Sjogren's syndrome: an autoimmune disorder affecting the salivary and lacrimal glands. In this disorder, immune cells attack host exocrine glands that are responsible for the production of tears and saliva.

Smac/Diablo: a mitochondrial protein that promotes some forms of apoptosis by neutralizing one or more members of the IAP family of apoptosis inhibitory proteins.

substantia nigra pars compacta (SNpc): the portion of the substantia nigra within the midbrain that encompasses the dopaminergic neurons which innervate the caudate nucleus and putamen of the basal ganglia. This area of the brain plays an important role in the pleasure/reward system and in addiction. Additionally, degeneration of the neurons in this area of the brain is an indicator of Parkinson's disease.

suppressor of cytokine signaling (SOCS) proteins: a family of proteins that inhibit the JAK-STAT signaling pathway by competitively binding to phosphotyrosine binding sites on cytokine receptors.

superoxide dismutase-1, copper-zinc superoxide dismutase (SOD1): a cytoplasmic enzyme that works as an antioxidant converting superoxide to oxygen and hydrogen peroxide. Mutations in the enzyme have been shown to be a factor in the motor neuron disease amyotrophic lateral sclerosis (ALS).

soman: an extremely toxic long acting organophosphorus compound with prominent inhibitory effects on acetylcholinesterase causing interference with nerve functioning

somatic hypermutation: point mutations that occur in cycling centroblasts and are targeted to the immunoglobulin variable-region gene segments. Some mutations might generate a binding site with increased affinity for the specific antigen, but others can lead to loss of antigen recognition by the B-cell

receptor and generation of a self-reactive B-cell receptor. Each mutation occurs only within individual cells and the mutations are not passed on to offspring.

Sox4: a member of the SOX (SRY-related HMG-box) family of transcription factors involved in the regulation of embryonic development and in the determination of the cell fate. The encoded protein may act as a transcriptional regulator after forming a protein complex with other proteins, such as syndecan binding protein (syntenin). The protein may also function in the apoptosis pathway leading to cell death as well as to tumorigenesis and may mediate downstream effects of parathyroid hormone (PTH) and PTH-related protein (PTHrP) in bone development.

spatial memory: a type of memory responsible for recording information about one's environment and its spatial orientation. For example, a person's spatial memory is required in order to navigate around a familiar city, just as a rat's spatial memory is needed to learn the location of food at the end of a maze.

STAT4: a member of the STAT family of transcription factors. In response to cytokines and growth factors, STAT family members are phosphorylated by the receptor associated kinases, and then form homo- or heterodimers that translocate to the cell nucleus where they act as transcription activators. This protein is essential for mediating responses to IL-12 in lymphocytes, and regulating the differentiation of T helper cells.

STAT6: protein that plays a central role in exerting IL-4 mediated biological responses. It is found to induce the expression of BCL2L1/BCL-X(L), which is responsible for the anti-apoptotic activity of IL-4. Knockout studies in mice suggested the roles of this gene in the differentiation of T helper 2 (Th2) cells, expression of cell surface markers, and class switching of immunoglobulins.

stem cell: a single cell that can differentiate along multiple lineages and can self-renew throughout the life of an organism while maintaining its differential capability. The three primary categories of stem cells are embryonic stem cells (originating from blastocysts), adult stem cells (derived from adult tissues), and cord blood stem cells (found in the umbilical cord).

stem cell therapy: Treatments and related research involving the use of undifferentiated cells which have self-renewal capacity and the unique potential to produce any kind of cell in the body.

stress: any physical or psychological stimulus that disrupts homeostasis.

striatum: a continuous part of the basal ganglia comprised of the caudate nucleus and putamen. This portion of the brain plays roles in modulating movement pathways as well as taking part in a variety of cognitive functions.

stroke: brain injury caused by occlusion or rupture of blood vessels into or around the brain causing a subsequent loss of oxygen and glucose to the affected brain area. Stroke is commonly termed a “cerebrovascular accident” or a “brain attack” and can cause severe neurological damage or death.

stromal cell-derived factor 1 (SDF-1): the ligand for CXCR4 receptor, this CXC chemokine (also designated CXCL12) is involved in chemotaxis, brain development, and immune cell recruitment.

subgranular zone: a brain region deep within the hippocampal parenchyma, at the interface between the granule cell layer and the hilus of the dentate gyrus, where adult neurogenesis occurs. It is one of the two major known adult neurogenesis sites of the brain, along with the subventricular zone.

subluxation: partial dislocation of a joint or organ.

substantia nigra: A layer of large pigmented nerve cells in the midbrain that produce dopamine and whose destruction is associated with Parkinson’s disease.

subventricular zone: a paired brain structure situated throughout the lateral walls of the lateral ventricles. Along with the subgranular zone of dentate gyrus, this zone serves as a source of neural stem cells in the process of adult neurogenesis. It harbors the largest population of proliferating cells in the adult brain of rodents, monkeys and humans. Neurons generated in this zone travel to the olfactory bulb via the rostral migratory stream.

susceptibility gene: a gene with multiple polymorphic forms, of which one or more forms causes differences in the processing or function of the gene that makes an individual more susceptible to a specific disease, but only in the presence of other interacting or contributing susceptibility genes or environmental factors.

sympathetic: the division of the autonomic nervous system that regulates various body functions and is always active on a basal level, but becomes more active during periods of stress and/or exertion. It causes the “fight-or-flight” response during times of stress by promoting the release of adrenaline and noradrenaline which bind to adrenergic receptors in peripheral tissues and cause such reactions and increased heart rate and blood pressure and pupil dilation.

symptomatic therapy: treatment or remedy for physical disturbance observed by the patient due to an underlying disease. Also called palliative care, this form of treatment does not address the basic cause or provide a cure for the underlying disease but rather focuses on preventing or easing suffering associated with the disease.

synapse: from the Greek meaning “to grasp,” a junction between two neural cells where the cell body (or dendrite) of one nerve is positioned across a small gap from the axon of

another nerve. Signal transmission occurs across these gaps via neurotransmitters, allowing the neurons to communicate with each other through the conversion of electrical impulses into chemical signals.

systems biology: a field of science that studies the interactions between the components of biological systems and how these interactions give rise to the function and behavior of that system.

T

tacrolimus: a macrolide antibiotic that acts as a calcineurin inhibitor to hinder T cell signal transduction and IL-2 transcription. It is an immunosuppressive agent that is used mainly to prevent rejection during allogeneic organ transplantation.

T-bet: T-box genes encode transcription factors involved in the regulation of developmental processes. This gene is the human ortholog of mouse Tbx21/Tbet gene. Studies in mouse show that Tbx21 protein is a Th1 cell-specific transcription factor that controls the expression of the hallmark Th1 cytokine, IFN γ . Expression of the human ortholog also correlates with IFN γ expression in Th1 and natural killer cells, suggesting a role for this gene in initiating Th1 lineage development from naive Th precursor cells.

T-cell receptor (TCR): a heterodimeric molecule found on the surface of T lymphocytes (T-cells) that is responsible for recognizing antigens bound to major histocompatibility complex (MHC) molecules. Upon antigen-receptor binding with MHC, a series of biochemical reactions occur which activate the associated T-cell.

T-cells: T (thymus derived) cell. These white blood cells, known as T lymphocytes, mature in the thymus and have regulatory immune functions. As part of the adaptive (cell-mediated) immune system, these cells can recognize antigens processed by antigen-presenting cells in the context of specific receptors. The cell surface protein CD3 is a marker for these cells.

terbutaline: a norepinephrine derivative that mimics norepinephrine action primarily at the subtype two beta adrenergic receptor. This compound is used as a bronchodilator and tocolytic.

temporal lobe: either of two lobes of the brain, located on either side of the cerebral hemisphere and part of the cerebrum. This portion of the brain is involved in auditory processing, semantics, and also contains the hippocampus which is responsible for learning and memory.

Th1 cells: also called inflammatory CD4 T cells, a subset of T cells that secrete the cytokines IL-2, IFN γ , and lymphotoxin and are most useful against intracellular pathogens that are best attacked by a cell-mediated response involving macrophage and granulocyte activation.

Th2 cells: also called helper CD4 T cells, a subset of T cells that secrete the cytokines IL-4, IL-5, and IL-10, and induce antibody and allergic responses that are useful for combating infections.

Th1/Th2 balance: according to the Th1/Th2 paradigm, naïve CD4⁺ T helper cells can be activated to differentiate into two types of effector cells: either Th1 or Th2 cells. In general, macrophages and dendritic cells tend to stimulate the Th1 differentiation, whereas extracellular antigens tend to stimulate Th2 cell differentiation. Th1 cells in turn stimulate macrophages and induce IgG production by B cells, while Th2 cells stimulate the humoral immune response including IgA, IgE, and certain IgG subtypes. An imbalance between Th1 and Th2 cells is observed in several immunological disease conditions; typical examples are Th1 predominance in rheumatoid arthritis and Th2 predominance in IgE-mediated allergy.

Th1/Th2: subclasses of T helper cells that are distinguished by their cytokine profiles. Th1 cells are characterized by production of IFN- γ . Th1 cells are characterized by production of IL-4. Th2 cells polarize the immune response towards cellular immunity and Th2 cells polarize towards antibody formation.

thalidomide: a drug originally used to treat morning sickness during pregnancy that caused severe limb deformities. This compound downregulates TNF α and is under investigation for treatment of severe Crohn's syndrome and other autoimmune disorders.

therapeutics: a branch of medical science dealing with the application of remedies to diseases.

tissue profiling: a tool for rapid detection of molecules, usually proteins and peptides, obtained directly from intact tissues to identify pathological changes.

T lymphocyte or T cell: Please see "T cell."

tolerance: refractoriness to physiological effects of a stimulus which develops with prolonged exposure, such as with drug tolerance. Alternatively, the failure of the immune system to react to an antigen, such as in the case of tolerance to self-antigens

toll-like receptors (TLR): a class of single membrane-spanning non-catalytic receptors that recognize structurally conserved molecules derived from microbes and activate immune cell responses. TLRs are believed to play a key role in the innate immune system. They are a type of pattern recognition receptors (PRRs) and recognize molecules that are broadly shared by pathogens but distinguishable from host molecules, collectively referred to as pathogen-associated molecular patterns (PAMPs). These receptors are present in both vertebrates and invertebrates and have similarities with receptors found in bacteria and plants. Due to this, these receptors are thought to be one of the oldest and most conserved components of the immune system.

transcription nuclear factor- κ -B: a protein complex found in all cell types that is involved in cellular responses to stimuli such as stress, cytokines, and foreign antigens. This transcription factor plays a regulatory role in immune response to infection and has also been suggested to be involved in processes of synaptic plasticity and memory. When improperly regulated, this transcription factor has also been implicated in causing cancer, autoimmune diseases, and other immune system malfunctions.

transducin: G protein expressed in retinal photoreceptor cells that is activated upon absorption of a photon by opsin. Activation of this protein stimulates cGMP-specific phosphodiesterase which leads to the vertebrate phototransduction cascade.

transgene: a segment of DNA (generally coding DNA) which is taken from one cell or organism and is introduced into different cells or organisms to modify a phenotype.

transmembrane protein transport (diffusion): the process of moving proteins from one cellular compartment (including extracellular) to another by various sorting and transport mechanisms such as gated transport, protein translocation, and vesicular transport. The tendency of a gas, solute or protein is to pass from a point of higher pressure or concentration to a point of lower pressure or concentration and to distribute itself throughout the available space:

transport: movement or transference of biochemical substances that occurs in biological systems.

trimethaphan: a synthetic compound which blocks the effect of acetylcholine at autonomic ganglia thereby blocking the sympathetic and parasympathetic nervous system. This compound has been used to reduce bleeding during neurosurgery, as well as to treat such emergencies as pulmonary edema and hypertensive crisis.

tropicamide: an atropine derivative which blocks the action of acetylcholine on muscarinic cholinergic receptors. This compound is often used during eye examinations to dilate the pupil and may also be used before or after eye surgery.

Trk receptor: cell surface proteins that are involved in transducing the actions of neurotrophins to promote neuronal survival, proliferation, migration, axonal and dendritic outgrowth and patterning, synapse strength and plasticity, injury protection, as well as controlling the activity of ion channels and neurotransmitter receptors.

tryptophan: L-tryptophan (TRP) is an essential amino acid, present in nearly all natural proteins. It is the precursor of the neurotransmitters serotonin and melatonin and of kynurenine, which is quantitatively the most important TRP metabolite.

tumor necrosis factor: serum glycoprotein produced by activated macrophages and other mammalian mononuclear leukocytes that acts as a cytokine to help stimulate inflammation and the acute phase reaction of the immune system. It has nec-

rotizing activity against tumor cell lines and increases ability to reject tumor transplants. Also known as TNF-alpha, it is only 30% homologous to TNF-beta (lymphotoxin), but they share TNF receptors. Disregulation of this cytokine has been implicated in causing cancer, among other human diseases.

tyramine: the decarboxylated form of the amino acid tyrosine which is present in food (e.g., cheese, beer, wine) and promotes the release of norepinephrine from sympathetic nerve endings. Significant displacement of norepinephrine by this compound when ingested in large quantities or while taking monoamine oxidase inhibitor medication is thought to cause vasoconstriction and increased heart and blood pressure.

U

urocortins: most recently discovered peptides belonging to the corticotropin-releasing factor family whose functions are generally unknown, but may play roles in immune function in addition to having anorexigenic and hypotensive effects, among other functions.

V

vaccination: the introduction of antigenic stimulants to the immune systems of humans or animals for the purpose of inducing the artificial development or regulation of immunity. Multiple kinds of vaccines exist to serve this purpose including inactivated, live attenuated, subunit, and DNA vaccines.

varicella zoster virus (VZV): an alpha human herpesvirus that causes the diseases chickenpox and, if later reactivated, shingles. A vaccine is currently available against the virus.

vector: a “vehicle,” such as a modified virus or DNA molecule, used to deliver genetic material into the body for gene therapy. Alternatively, an organism that does not cause disease itself but can transmit infection through transferring pathogens among different hosts (such as a mosquito).

vehicle: a type of adjuvant that possesses no medicinal action of its own, but delivers or targets an antigen to cells of the immune system.

vimentin: a member of the intermediate filament family of proteins that is an important component of eukaryotic cell cytoskeletons. These proteins are responsible for cell flexibility and resilience under mechanical stress as well as the transport of low density lipoprotein intended to undergo esterification.

visual-evoked potential-(VEP) viruses: minute infectious agents whose genomes are composed of DNA or RNA, but not both. They are characterized by a lack of independent metabolism and the inability to replicate outside living host cells.

W

withdrawal: signs and symptoms that occur as a result of a discontinuation of certain activities or drugs (such as opioids) and includes perturbations in various physiological systems that are indications of physical dependence.

- Transforming growth factor- β , 184
- Trastuzumab, 636
- Trazadone, 571
- Tremor
- essential, 229, 231
 - Parkinson disease-related, 570, 571, 572
- Tricarboxylic acid (TCA) cycle, 71, 72
- Trichromacy, 126
- Trichromatic vision, 129
- Tricyclic antidepressants, 570, 571
- interaction with antiretroviral agents, 612
- Trihexyphenidyl, 568
- Trk receptors, 184
- Trk receptor signaling, 208
- Trophic factors, 576
- in neurodegeneration, 7
 - in neuronal injury response, 18
- Tryptophan
- deficiency of, 514
 - effect of cytokines on, 513
 - in major depression, 516–517
- D-Tubocurarine, 549
- Tumor growth factor- β
- cyclosporine-enhanced production of, 558
 - effect on Treg cells, 666
 - in human immunodeficiency virus-related dementia, 190
 - in neural stem cell proliferation, 153
- Tumor growth factor- β 1
- in anterior chamber-associated immune deviation, 42
 - in bipolar disorder, 504
- Tumor growth factor- β 2
- in anterior chamber-associated immune deviation, 42
- Tumor necrosis factor(s)
- blood-brain barrier transport of, 27, 28
 - in central nervous system injuries, 30
 - p-glycoprotein-regulatory activity of, 30
 - transport to the brain, 22
- Tumor necrosis factor- α , 94, 159, 184
- cyclooxygenase-2 inhibitor-related decrease in, 520–521
 - cytokines in, 191
 - in depression, 487, 489, 513–514
 - in human immunodeficiency virus-related dementia, 189, 190
 - interaction with antidepressants, 515
 - long-term potentiation-inhibiting effects of, 61
 - in multiple sclerosis, 243, 247
 - in neurogenesis, 454
 - opioid receptor agonist-related inhibition of, 553–554
 - in Parkinson's disease, 370
 - as psoriatic arthritis cause, 290
 - in sleep deprivation, 515
 - sources of, 187
- Tumor necrosis factor- α inhibitors
- as Reiter's syndrome treatment, 290
 - as rheumatoid arthritis treatment, 287
- Tumor necrosis factor- β , 184, 454
- Tumor necrosis factor-receptor p55, 513
- Tumor necrosis factor receptor polymorphisms, 606
- Tumor necrosis factor-related apoptosis-inducing ligand, 184, 190, 191, 217
- Tumor necrosis factor superfamily, 184, 217
- Twin studies
- of bipolar disorder, 502
 - of depression, 497
 - of genetic diseases, 464
 - of multiple sclerosis, 242, 471
- Type A cells, 160
- Type B cells, 447, 448
- Type C cells, 160, 447, 448
- Type 1 cells, 448
- Type 2 cells, 448
- Type 3 cells, 448
- Tyramine, 549
- Tyrosine hydroxylation, 549
- ## U
- Uhthoff's phenomenon, 244
- Urocortins, 486–487
- Uveitis
- ankylosing spondylitis-related, 289
 - cyclosporine treatment of, 558
 - experimental autoimmune, 49–50
- ## V
- Vaccination/vaccines, 715–718
- active, 717
 - as amyotrophic lateral sclerosis treatment, 642
 - CD4+CD25+ T cell-based, 670
 - dendritic cell-based, 99–100
 - lymphopenia-based, 669–670
 - memory cells and, 145
 - as neurodegenerative disease treatment, 624–626
 - as Parkinson's disease treatment, 642
 - passive, 716–717
 - self-antigen agonists-based, 669
 - single-chain antibody-based, 651–652
- Vagus nerve, 551
- Valacyclovir
- adverse effects of, 332
 - comparison with acyclovir, 332, 338
 - as encephalitis treatment, 328
 - as herpes zoster (shingles) treatment, 332
 - as herpes zoster treatment, 330
- Valproate/valproic acid, 503, 570, 571
- Varicella (chickenpox), 329–330, 332

Varicella-zoster virus infection
 as encephalitis cause, 329–330
 treatment of, 332
Varicella-zoster virus vaccine, 329
Vascular endothelial growth factor, 156, 157, 161, 184, 470, 576
Vasculitis, 283–284
 rheumatoid, 286–287
Vasoactive intestinal protein, 549, 642, 650
Ventriculoencephalitis, 331
Verapamil, 578
Vertebral arteries, 17
Vimentin, 447
Viral infections. *See also specific viruses*
 leukocyte recruitment into, 621
 as multiple sclerosis cause, 242–243, 251, 292
 prenatal, as schizophrenia cause, 489
Viral integrase inhibitors, 608
Viral replication, in human immunodeficiency virus-related dementia, 607
Virchow, Rudolph, 70, 105
Viruses. *See also specific viruses*
 blood-brain barrier transport of, 28
 central nervous system reservoir of, 30
 neuroinflammatory, 213
 neuroinvasion by, 26
Vision
 neuroanatomical basis of, 11, 12
 scotopic (low-light), 130, 132
Visna virus, 243, 302
Visual acuity, 126, 130
 multiple sclerosis-related loss of, 244
Visual cortex, 14, 46, 47, 48
Visual fields, 47, 48
Visual field testing, 423–424
Visual pathways, anatomy and physiology of, 44–48

Vitamin E, 575
Vitreoretinopathy, 98–99

W

Water balance, astrocytes in, 71
Wegener's granulomatosis, 558
Wernicke's area, anatomy and function of, 11
West Nile virus, 327, 334–335, 335, 337
White matter
 anatomy of, 13
 in human immunodeficiency virus infection, 302, 607
 oligodendrocytes in, 18
Whole genome association analysis, 465
Wild animals, as rabies virus vectors, 337
Wine, tyramine content of, 549
Wnt (Wingless) signaling molecule, 154, 452
World Health Organization (WHO) staging system, for human immunodeficiency virus-associated dementia, 605
Wound healing, 663
Wybran, Joseph, 531–532

X

X-adrenoleukodystrophy, 80
X cells, retinal, 128

Y

Y cells, retinal, 128
Yersinia infections, 289–290
YSFKPMPLaR, as molecular adjuvant, 683–686

Z

Zalcitabane, 610, 613
Zidovudine, 609, 610, 611, 616
 adverse neurological effects of, 611
 comparison with nimodipine, 613
 interaction with sodium valproate, 612
